THE AMERICAN ECONOMIC ASSOCIATION

Founded in 1885

• Published at George Banta Co., Inc., Menasha, Wisconsin.

• The American Economic Review, including four quarterly numbers, the *Proceedings* of the annual meetings, and *Directory* and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September, and December.

• Membership dues of the Association are $20.00 a year, which includes a year's subscription to both the *American Economic Review* and the *Journal of Economic Literature*. A three year junior membership of $10.00 per year is available to registered students. Subscriptions by nonmembers are $30.00 a year, and only subscriptions to both publications will be accepted. Single copies of the *Review* and *Journal* are $4.00 each. Each order for copies of either publication must also include a $.50 per order service charge. Orders should be sent to the Secretary's office, Nashville, Tennessee.

• Correspondence relating to the *Papers and Proceedings*, the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address may be sent to the secretary, Rendigs Fels, 1313 21st Avenue, South, Nashville, Tennessee 37212. To be effective, notice of change of address must reach the secretary by the 1st of the month previous to the month of publication. The Association's publications are mailed by second class and are not forwardable by the Post Office.

• Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.

THE AMERICAN ECONOMIC REVIEW

March 1973

VOLUME LXIII, NUMBER 1

• Manuscripts and editorial correspondence relating to the regular quarterly issue of this REVIEW should be addressed to George H. Borts, Managing Editor of THE AMERICAN ECONOMIC REVIEW, Brown University, Providence, R.I. 02912. Manuscripts should be submitted in duplicate and in acceptable form and should be no longer than 50 pages of double-spaced typescript. A $10 submission fee must accompany each manuscript. *Style Instructions* for guidance in preparing manuscripts will be provided upon request to the editor.

• No responsibility for the views expressed by authors in this REVIEW is assumed by the editors or the publishers, The American Economic Association.

EMPLOYMENT SERVICES

NATIONAL REGISTRY FOR ECONOMISTS

The National Registry for Economists was established in January, 1966, to provide a centralized nationwide clearinghouse for economsts on a year-round basis. It is located in the Chicago Professional Placement Office of the Illinois State Employment Service and is staffed by experienced placement personnel, operating under the guidance and direction of Regional and National Bureau of Employment Security Professional Placement officials, and in cooperation with the American Economic Association. It is a free service. The National Registry for Economists maintains completely separate listings from those of the American Economic Association, and the National Registry does *not* have the listings as shown in the *American Economic Review*. There are no registration, referral, or placement fees. Application and order forms used in the Registry are available upon request from the: National Registry for Economists, Professional Placement Center, 40 West Adams Street, Chicago, Illinois 60603.

AMERICAN ECONOMIC ASSOCIATION
VACANCIES AND APPLICATIONS

The Association renders this service to economists who wish to make known their availability for positions and to those who are seeking to fill vacancies in the field of economics. The Association takes no responsibility for selecting applicants or for following up the results. The Secretary's office will merely afford a central point for forwarding inquiries. The *Review* will publish a description of vacancies and applications submitted, with necessary editorial changes. The Secretary would appreciate receiving notification of appointments made as a result of this service. All inquiries about a listing with a key number should refer to it specifically. Communications should be addressed to: The Secretary, American Economic Association, 809 Oxford House, 1313 21st Avenue South, Nashville, Tennessee 37212.

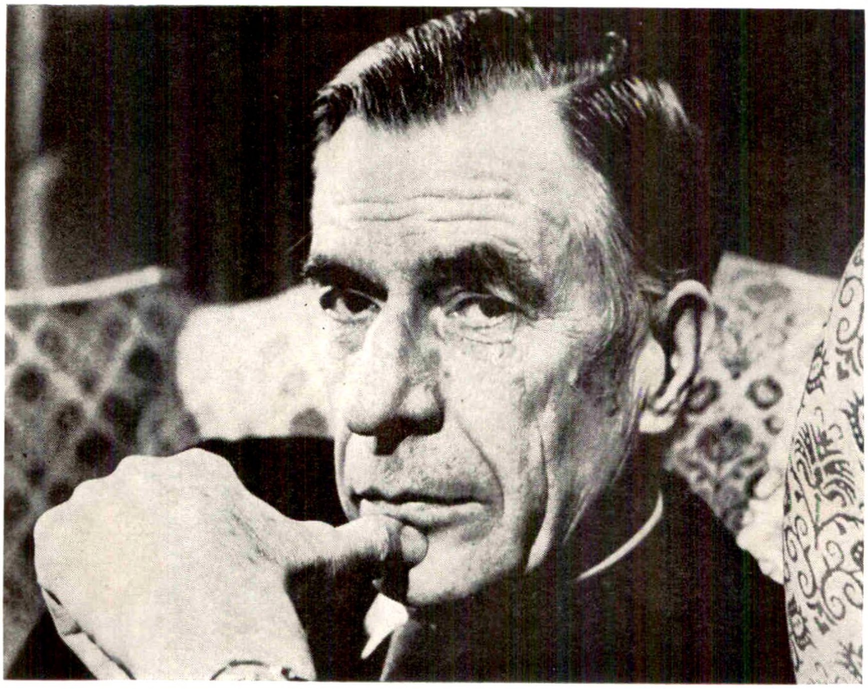
Résumés and application blanks are *not* supplied by the American Economic Association. The Secretary's office will merely forward any announcements of positions or résumés received to a designated key number. Deadlines for the four issues of the *Review* are January 1, April 1, July 1, and October 1. Announcements will normally be printed in two consecutive issues.

Vacancies

Academic Appointments: School of Comparative Social Sciences, Universiti Sains Malaysia (formerly known as the University of Penang); Senior Lecturers/Lecturers in international economics, regional economics, mathematical economics/econometrics/economic statistics, monetary and fiscal economics, development planning, intermediate economic theory, business administration. Salary range: Senior Lecturers from $22,380 (US $7932) to $30,120 (US $10680) per annum; Lecturers, from $16,800 (US $5964) to $26,580 (US $9420) per annum. Fringe benefits include return air passages and free medical coverage for appointee and family. Write to: The Registrar, Universiti Sains Malaysia, Minden, Pulau Pinang, Malaysia.

Economic Fellows: Senator Bill Brock announces fellowships for advanced graduate students, college professors or other professionals actually working within their area of expertise. Fellows would be expected to provide substantive materials leading to policy statements and legislation. Financial assistance is sometimes available for fellows at the rate of $4,000 to $5,000 a year. Fellows will generally remain in Senator Brock's office for at least six months. Application dates are open. Please send curriculum vitae, example of written work, and a description of your substantive interests to: Harrison Fox, Office of Senator Bill Brock, 304 Old Senate Office Building, Washington, D.C. 20510.

Number 74 of a series of photographs of past presidents of the Association



Power and the Useful Economist

By John Kenneth Galbraith*

The ceremonial address of the President of the American Economic Association is an art form which, I imagine like most of my predecessors, I have thoughtfully reviewed. On occasion, in the past, the addresses have dealt with some substantive problem of our subject or some afflicting problem of the economy. More often they have dealt, always a shade critically, with the methodology of economics. While accepting the larger science there has been adverse comment on the detailed elements of its practice. Economics is insufficiently normative. Model building has become an end, not a means. For several recent years in succession the criticism—which involved a certain element of personal introspection—included an exceptionally grave attack on mathematical economics. The style of these addresses, I might note in passing, is as distinctive as the subject matter. It features the thoughtful solemnity of men who sense that we are speaking for the ages. It may be worth a moment's time, on these great occasions, to recall that ours is a subject which features defeated expectations.

I am moved this evening to depart from the established rites. I should like to concern myself with basic questions of assumption and structure. If this breaks with tradition, it does not break with present professional tendency. We meet at a time when criticism is general—when the larger body of established theory is under extensive attack. Within the last half-dozen years what before was simply called economics in the nonsocialist world has come to be designated neoclassical economics with appropriate overtures to the Keynesian and post-Keynesian development. From being a general and accepted theory of economic behavior this has become a special and debatable interpretation of such behavior. For a new and notably articulate generation of economists a reference to neoclassical economics has become markedly pejorative.

I would judge as well as hope that the present attack will prove decisive. The established theory has reserves of strength. It sustains much minor refinement which does not raise the question of overall validity or usefulness. It survives strongly in the textbooks although even in this stronghold one senses anxiety among the more progressive or commercially sensitive authors. Perhaps there are limits to what the young will accept.

And the arrangements by which orthodoxy is conserved in the modern academy also remain formidable. In its first half century or so as a subject of instruction and research, economics was subject to censorship by outsiders. Businessmen and their political and ideological acolytes kept watch on departments of economics and reacted promptly to heresy, the latter being anything that seemed to threaten the sanctity of property, profits, a proper tariff policy, a balanced budget, or which involved sympathy for unions, public ownership, public regulation or, in any organized way, for the poor. The growing power and self-confidence of the educational estate, the formidable and growing complexity of our subject and, no doubt, the increasing acceptability of our ideas has largely relieved us of this intervention.

* Presidential address delivered at the eighty-fifth meeting of the American Economic Association, Toronto, Canada, December 29, 1972.

In leading centers of instruction faculty responsibility is either secure or increasingly so. But in place of the old censorship has come a new despotism. That consists in defining scientific excellence as whatever is closest in belief and method to the scholarly tendency of the people who are already there. This is a pervasive and oppressive thing not the less dangerous for being, in the frequent case, both self-righteous and unconscious.

But there are problems even with this control. Neoclassical or neo-Keynesian economics, though providing unlimited opportunity for demanding refinement, has a decisive flaw. It offers no useful handle for grasping the economic problems that now beset the modern society. And these problems are obtrusive—they will not lie down and die as a favor to our profession. No arrangement for the perpetuation of thought is secure if that thought does not make contact with the problems that it is presumed to solve.

I will not omit this evening to mention the failures of neoclassical theory. But I want also to urge the means by which we can reassociate ourselves with reality. Some of this will summarize past argument, more a book that is presently to be published. At this stage even the most conservative among my listeners will be reassured. To speak well of one's own published and unpublished writing, whatever one's other aberrations, is strongly in our professional tradition.

I

The most commonplace features of neoclassical and neo-Keynesian economics are the assumptions by which power, and therewith political content, is removed from the subject. The business firm is subordinate to the instruction of the market and, thereby, to the individual or household. The state is subordinate to the instruction of the citizen. There are exceptions but these are to the general and controlling rule, and it is firmly on the rule that neoclassical theory is positioned. If the business firm is subordinate to the market—if that is its master—then it does not have power to deploy in the economy save as this is in the service of the market and the consumer. And the winning of action to influence or rig the behavior of markets apart, it cannot bring power to bear on the state for there the citizen is in charge.

The decisive weakness in neoclassical and neo-Keynesian economics is not the error in the assumptions by which it elides the problem of power. The capacity for erroneous belief is very great, especially where it coincides with convenience. Rather in eliding power—in making economics a nonpolitical subject—neoclassical theory, by the same process, destroys its relation with the real world. The problems of this world, moreover, are increasing both in number and in the depth of their social affliction. In consequence neoclassical and neo-Keynesian economics is relegating its players to the social sidelines where they either call no plays or urge the wrong ones.

Specifically the exclusion of power and the resulting political content from economics causes it to foretell only two intrinsic and important economic problems. One of these is the microeconomic problem of market imperfection—more specifically of monopoly or oligopoly in product or factor markets—leading to aberration in resource and income distribution. The other is the macroeconomic problem of unemployment or inflation—of a deficiency or excess in the aggregate demand for goods and services, including that associated with monetary effects. And on both problems the failure is dramatic. Neoclassical economics leads to the wrong solution of the microeconomic problem and to no solution of the macroeconomic

problem. Meanwhile it leaves a whole galaxy of other urgent economic issues largely untouched.

It is now the considered sense of the community, even of economists when unhampered by professional doctrine, that the most prominent areas of market oligopoly—automobiles, rubber, chemicals, plastics, alcohol, tobacco, detergents, cosmetics, computers, bogus health remedies, space adventure—are areas not of low but of high development, not of inadequate but of excessive resource use. And there is a powerful instinct that in some areas of monopoly or oligopoly, most notably in the production of weapons and weapons systems, resource use is dangerously vast.

In further contradiction of the established microeconomic conclusions, we have an increasing reaction by the community to deficient resource use in industries that, at least in the scale and structure of the firm, approach the market model. Housing, health services, and local transportation are among the leading cases. The deprivation and social distress that follow from the poor performance of these industries are also something that, in their nondoctrinal manifestation, most economists take for granted.

The defender of the established doctrine does, of course, argue that excess and deprivation in resource use in the areas just mentioned reflect consumer choice. And in the areas of deprivation he can rightly insist that the fault lies with firms that, though small, are local monopolies or reflect the monopoly power of unions. These explanations beg two remarkably obvious questions: Why does the modern consumer increasingly tend to insanity, increasingly insist on self-abuse? And why do little monopolies perform badly and the big ones too well?

In fact the neoclassical model has no explanation of the most important microeconomic problem of our time. That problem is why we have a highly unequal development as between industries of great market power and industries of slight market power, with the development, in defiance of all doctrine, greatly favoring the first.[1]

The macroeconomic failure has been, if anything, more embarrassing. Save in its strictly mystical manifestation in one branch of monetary theory, modern macroeconomic policy depends for its validity and workability on the neoclassical market. That market, whether competitive, monopolistic, or oligopolistic, is the ultimate and authoritative instruction to the profit-maximizing firm. When output and employment are deficient, policy requires that aggregate demand be increased; this is an instruction to the market to which firms in turn respond. When the economy is at or near the effective capacity of the plant and the labor force and inflation is the relevant social discomfort, the remedy is reversed. Demand is curtailed; the result is either an initial effect on prices or a delayed one as surplus labor seeks employment, interest rates fall and lower factor costs bring stable or lower prices.

Such is the accepted basis of policy. It follows faithfully from the neoclassical faith in the market. The practical consequences of pursuing it need no elucidation. It has been tried in recent years in every developed country. The common result has been politically unacceptable unemployment, persistent and (in my view) socially damaging inflation or, more often, a combination of the two. The extreme failure has been, not surprisingly, in the most advanced industrial country,

[1] It will be observed that performance in agriculture, an industry in which the firm has little market power, is not adverse. But it should also be observed that in no industry has power over prices been more completely removed to public authority or is there greater effort at collective control of costs or a more comprehensive socialization of technology.

the United States. But the recent experience of Britain has been almost equally disenchanting. One gathers that there may be Canadian politicians who now believe that a combination of unemployment and inflation is not the best platform on which to fight a general election.

We should not deny ourselves either the instruction or the amusement that comes from the recent history of the United States in this matter. Four years ago Mr. Nixon came to office with a firm commitment to neoclassical orthodoxy. In this he was supported by some of its most distinguished and devout exponents in all the land. His subsequent discovery that he was a Keynesian involved no precipitate or radical departure from this faith. The discovery came thirty-five years after *The General Theory*; as I have just noted, all neo-Keynesian policy rests firmly on the paramount role of the market. But then a year and a half ago, facing reelection, he found that his economists' commitment to neoclassical and Keynesian orthodoxy, however admirable in the abstract, was a luxury that he could no longer afford. He apostatized to wage and price control; so, with exemplary flexibility of mind, did his economists although admittedly this acceptance of the real world has still to survive its critical test which is the apostates' return to computers and classrooms. But our admiration for this pliability should not keep us from recalling that, when the President changed course, no American economists were anywhere working on the policy he was forced by circumstances to adopt. And it is even more disturbing that few are now working on the policy which we have been forced to follow.

More economists, in fact, are still concerning themselves with the effort to reconcile controls with the neoclassical market. This has involved an unrewarding combination of economics and archeology with wishful thinking. It holds that an inflationary momentum developed during the late 1960's in connection with the financing—or underfinancing—of the Vietnam war. And inflationary expectation became part of business and trade union calculation. The momentum and expectation still survive. The controls are necessary until these are dissipated. Then the neoclassical and neo-Keynesian world will return, along with the appropriate policies, in all their quiet comfort. We may be sure that will not happen. Nor will we expect it to happen if we see the role of power and political decision in modern economic behavior.

II

In place of the market system, we must now assume that for approximately half of all economic output there is a power or planning system. (The latter term seems to me more descriptive, less pejorative and thus preferable.) The planning system consists in the United States of, at the most, 2,000 large corporations. In their operation they have power that transcends the market. They rival where they do not borrow from the power of the state. My views on these matters will be familiar at least to some, and I shall spare myself the pleasure of extensive repetition. I cannot think that the power of the modern corporation, the purposes for which it is used or the associated power of the modern union would seem implausible or even very novel were they not in conflict with the vested doctrine.

Thus we agree that the modern corporation either by itself or in conjunction with others, has extensive influence over its prices and its major costs. Can we doubt that it goes beyond its prices and the market to persuade its customers? Or that it goes back of its costs to organize supply? Or that from its earnings or the possession of financial affiliates it seeks to

control its sources of capital? Or that its persuasion of the consumer joined with the similar effort of other firms—and with the more than incidental blessing of neoclassical pedagogy—helps establish the values of the community, notably the association between well-being and the progressively increased consumption of the products of this part of the economy?

And as citizens, if not as scholars, we would not deny that the modern corporation has a compelling position in the modern state. What it needs in research and development, technically qualified people, public works, emergency financial support, becomes public policy. So does the military procurement that sustains the demand for numerous of its products. So, perhaps, does the foreign policy that justifies the military procurement. And the means by which this power is brought to bear on the state is widely accepted. It requires an organization to deal with an organization. And between public and private bureaucracies—between GM and the Department of Transportation, General Dynamics and the Pentagon—there is a deeply symbiotic relationship. Each of these organizations can do much for the other. There is even, between them, a large and continuous interchange of executive personnel.

Finally over this exercise of power and much enhancing it is the rich gloss of reputability. The men who guide the modern corporation, including the financial, legal, technical, advertising, and other sacerdotal authorities in corporate function, are the most respectable, affluent, and prestigious members of the national community. They are the Establishment. Their interest tends to become the public interest. It is an interest that even some economists find it comfortable and rewarding to avow.

That interest, needless to say, is profoundly concerned with power—with winning acceptance by others of the collective or corporate purpose. It does not disavow profits. These are important for ensuring the autonomy of the management—what I have called the technostructure—and for bringing the supply of capital within the control of the firm. Profits are also a source of prestige and therewith of influence. But of paramount importance is the much more directly political goal of growth. Such growth carries a strong economic reward; it directly enhances the pay, perquisites, and opportunities for promotion of the members of the technostructure. And it consolidates and enhances authority. It does this for the individual—for the man who now heads a larger organization or a larger part of an organization than before. And it increases the influence of the corporation as a whole.

Neoclassical economics is not without an instinct for survival. It rightly sees the unmanaged sovereignty of the consumer, the ultimate sovereignty of the citizen and the maximization of profits and resulting subordination of the firm to the market as the three legs of a tripod on which it stands. These are what exclude the role of power in the system. All three propositions tax the capacity for belief. That the modern consumer is the object of a massive management effort by the producer is not readily denied. The methods of such management, by their nature, are embarrassingly visible. It can only be argued that somehow it all cancels out. Elections in the United States and Canada are now being fought on the issue of the subordination of the state to corporate interest. As voters, economists accept the validity of the issue. Only their teaching denies it. But the commitment of the modern corporate bureaucracy to its expansion is, perhaps, the clearest of all. That the modern conglomerate always pursues profit over aggrandizement is believed by none. It is a commonplace of these last years, strongly

reflected in securities' prices, that agglomeration has always been good for growth but often bad for earnings.

There remains in the modern economy—and this I stress—a world of small firms where the instruction of the market is still paramount, where costs are given, where the state is remote and subject through the legislature to the traditional pressures of economic interest groups and where profit maximization alone is consistent with survival. We should not think of this as the classically competitive part of the system—in contrast with the monopolistic or oligopolistic sector from which the planning system has evolved. Rather, in its combination of competitive and monopolistic structures, it approaches the entire neoclassical model. We have, to repeat, two systems. In one, power is still, as ever, contained by the market. In another and still evolving system, power extends incompletely but comprehensively to markets, to the people who patronize them, to the state and thus, ultimately, to resource use. The coexistence of these two systems becomes, in turn, a major clue to economic performance.

III

Power being so comprehensively deployed in a very large part of the total economy, there can no longer, except for reasons of game-playing or more deliberate intellectual evasion, be any separation by economists between economics and politics. When the modern corporation acquires power over markets, power in the community, power over the state, power over belief, it is a political instrument, different in form and degree but not in kind from the state itself. To hold otherwise—to deny the political character of the modern corporation—is not merely to avoid the reality. It is to disguise the reality. The victims of that disguise are those we instruct in error. The beneficiaries are the institutions whose power we so disguise. Let there be no question: Economics, so long as it is thus taught, becomes, however unconsciously, a part of an arrangement by which the citizen or student is kept from seeing how he is, or will be, governed.

This does not mean that economics now becomes a branch of political science. That is a prospect by which we would rightly be repelled. Political science is also the captive of its stereotypes—including that of citizen control of the state. Also while economics cherishes thought, at least in principle, political science regularly accords reverence to the man who knows only what has been done before. Economics does not become a part of political science. But politics does—and must—become a part of economics.

There will be fear that once we abandon present theory, with its intellectually demanding refinement and its increasing instinct for measurement, we shall lose the filter by which scholars are separated from charlatans and windbags. These latter are always a danger, but there is more danger in remaining with a world that is not real. And we shall be surprised, I think, at the new clarity and intellectual consistency with which we see our world, once power is made a part of our system. To such a view let me now turn.

IV

In the neoclassical view of the economy a general identity of interest between the goals of the business firm and those of the community could be assumed. The firm was subject to the instruction of the community, either through the market or the ballot box. People could not be fundamentally in conflict with themselves—always given some reasonable decency in income distribution. Once the firm in the planning system is seen to have comprehensive power to pursue its own interest,

this assumption becomes untenable. Perhaps by accident its interests are those of the public but there is no organic reason why this must be so. In the absence of proof to the contrary, divergence of interest, not identity of interest, must be assumed.

The nature of the conflict also becomes predictable. Growth being a principal goal of the planning system it will be great where power is great. And in the market sector of the economy, growth will, at least by comparison, be deficient. This will not, as neoclassical doctrine holds, be because people have an amiable tendency to misunderstand their needs. It will be because the system is so constructed as to serve badly their needs and then to win greater or less acquiescence in the result. That the present system should lead to an excessive output of automobiles, an improbable effort to cover the economically developed sections of the planet with asphalt, a lunar preoccupation with moon exploration, a fantastically expensive and potentially suicidal investment in missiles, submarines, bombers, and aircraft carriers, is as one would expect. These are the industries with power to command resources for growth. And central to public purpose—to sound resource utilization—will be a cutback in such industries, as all instinct now suggests. Thus does the introduction of power as a comprehensive aspect of our system correct present error. Let us not fail to note that these are exactly the industries in which an uncomplicated neoclassical view of monopoly and oligopoly and of profit maximization at the expense of ideal resource use would, of all things, suggest an expansion of output. How wrong are we allowed to be!

The counterpart of excessive resource use in the planning system where power is comprehensively deployed is a relatively deficient resource use where power is circumscribed. Such will be the case in the part of the economy where competition and entrepreneurial monopoly as distinct from great organization are the rule. And if the product or service is closely related to comfort or survival, the discontent will be considerable. That housing, health services, local transportation, some household services, are now areas of grave inadequacy is agreed. It is in such industries that all modern governments seek to expand resource use. Here, in desperation, even the devout free enterprisers accept the need for social action, even of socialism.

Again, we may observe, the error of economics is prejudicial. Although as citizens we advocate restraint in the area of excessive resource use, our teaching does not. And though as citizens we urge social action where the firm approaches the neoclassical norm, our teaching does not. In this latter case we not only disguise corporate power but we make remedial action in such areas as housing, health care, transportation, also abnormal—the consequence of *sui generis* error that is never quite explained. This is unfortunate for here are tasks that require imagination, pride and determination.

V

When power is admitted to our calculus, our macroeconomic embarrassment also disappears. Economics makes plausible what governments are forced, in practice, to do. Corporations have power in their markets. So, and partly in consequence, do unions. The competitive claims of unions can most conveniently be resolved by passing the cost of settlement along to the public. Measures to arrest this exercise of power by limiting aggregate demand must be severe. And, not surprisingly, the power of the planning system has been brought to bear to exclude those macroeconomic measures that have a primary effect on that system. Thus monetary policy is entirely

permissible; that is at least partly because its primary effect is on the neoclassical entrepreneur who must borrow money. Monetary constraint is far less painful for the large established corporation which, as an elementary exercise of power, has ensured itself a supply of capital from earnings or financial affiliates or morally affiliated banks. The power of the planning system in the community has also won immunity for public expenditures important to itself—highways, industrial research, rescue loans, national defense. These have the sanction of a higher public purpose. A similar if still slightly less successful effort is being made on behalf of corporate and personal taxes. So fiscal policy has also been accommodated to the interests of the planning system.

Thus the inevitability of controls. The interaction of corporate and trade union power can be made to yield only to the strongest fiscal and monetary restraints. Those restraints that are available have a comparatively benign effect on those with power, but they weigh adversely on people who vote. When no election is in prospect, perhaps such a policy is possible. It will earn applause for its respectability. But it cannot be tolerated by anyone who must weigh its popular effect.

As with the need for social action and organization in the market sector there are many reasons why it would be well were economists to accept the inevitability of wage and price control. It would help keep politicians, responding to the resonance of their own past instruction, from supposing controls to be wicked and unnatural and hence temporary and to be abandoned whenever they seemed to be working. This is a poor mood in which to develop sound administration. And it would cause economists themselves to consider how controls can be made workable and how the effect on income distribution can be made equitable. With controls this last becomes a serious matter. The market is no longer a disguise for inequality, however egregious, in income distribution. Much inequality must be seen to be the result of relative power.

VI

When power is made part of our system, yet other matters of considerable current moment are illuminated. Thus the counterpart of systemic differences in development as between the planning and market sectors of the economy is systemic sectoral differences in income. In the neoclassical system, resource mobility is assumed, broadly speaking, to equalize inter-industry return. If there is inequality, it is the result of barriers to movement. Now we see that, given its comprehensive market power, the planning system can protect itself from adverse movements in its terms of trade. The same power allows it to accept unions for it need not absorb even temporarily their demands. In the market system, some areas of monopoly or union power apart, there is no similar control of the terms of trade. Given the absence of market power there can be no similar yielding on wage costs for there is no similar certainty that they can be passed on. (It is because of the character of the industry he seeks to organize, not his original power, that Cesar Chavez is for so many the new Lenin.) And, in the market system, the self-employed have the option —not present in the planning system—of reducing their own wages (and sometimes those of families or immediate employees) in order to survive.

Thus there is a built-in inequality in income between the two systems. And thus also the case for minimum wage legislation, support to trade unions in agriculture, price support legislation, and most important, perhaps, a floor under family income as antidotes to such inter-

industry inequality. Again this view of matters fits our present concerns. Minimum wage legislation, price support legislation, and support to collective bargaining are all questions of continuing political controversy as they apply to small business and agriculture. They are not serious issues in highly organized industry—in the planning system. And the question of a floor under family income, a matter of intense political argument, has recently divided workers in the planning system who would not be beneficiaries from those in the market system who would be. Again there is reassurance in a view of the economy that prepares us for the politics of our time.

The inclusion of power in economic calculus also prepares us for the great debate over the environment. It is the claim of neoclassical economics that it foresaw possible environmental consequences from economic development—that it, some time ago, embraced the concept of external diseconomies of production and, by inference, of consumption. Alas, this is a modest claim. The noninclusion of external diseconomies was long viewed as a minor defect of the price system—an afterthought for an hour's classroom discussion. And, as E. J. Mishan has observed, it was largely ignored in the textbooks. Nor does the notion of external diseconomies now offer a useful remedy. No one can suppose, or really supposes, that more than a fraction of the damage—especially that to the beauty and tranquility of our surroundings—could be compensated in any useful way by internalizing external diseconomies.

If growth is the central and rewarding purpose of the firm and if power is comprehensively available to impose this goal on the society, the possibility of conflict between private growth and public purpose as regards the environment is immediately plausible. So, since this power depends extensively not on force but persuasion, is the effort to make pollution seem palatable or worth the cost, including the effort to make advertising of remedial action a substitute for action. And so is the remedy to which all industrial countries are being forced. This is not, primarily, to internalize external diseconomies. Rather it is to specify the legal parameters within which growth may proceed or, as in the case of automobile use in central cities, airplane use over urban areas, the SST, industrial, commercial, and residential appropriation of countryside and roadside, the kinds of growth that are inconsistent with public purpose. We would have saved much corruption of our surroundings if our economics had held such action to be the predictable consequence of the pursuit of present economic goals and not the exceptional result of a peculiar aberration of the price system.

We had best, in any case, have the right guide to action for the future for there is a strong conservative case for such guidance. While economists toy weakly with external diseconomies, others are arguing that growth itself is the villain. They are seeking its extinction. To see environmental damage as a natural consequence of planning power and purpose and to see, in consequence, the need for confining growth within parameters that protect the public interest could be important for ensuring continued economic growth.

Finally, when power becomes part of our system, so does Ralph Nader. We are prepared for the explosion of concern now called consumerism. If the consumer is the ultimate source of authority, his abuse is an occasional fault. He cannot be fundamentally at odds with an economic system that he commands. But if the producing firm has comprehensive power and purposes of its own, there is every likelihood of conflict. Technology is then subordinate to the strategy of consumer persuasion.

Products are changed not to make them better but to take advantage of the belief that what is new is better. There is a high failure rate in engineering not what is better but what can be sold. The consumer—the unpersuaded or disenchanted consumer—rebels. This is not a rebellion against minor matters of fraud or misinformation. It is a major reaction against a whole deployment of power by which the consumer is made the instrument of purposes that are not his own.

VII

There are two conclusions to which this exercise—to which incorporation of power into our system—compels us. The first, in a way, is encouraging. It is that economists' work is not yet done. On the contrary, it is just beginning. If we accept the reality of power as part of our system, we have years of useful work ahead of us. And since we will be in touch with real issues, and since issues that are real inspire passion, our life will, again, be pleasantly contentious, perhaps even usefully dangerous.

The other conclusion concerns the state. For when we make power and therewith politics a part of our system, we can no longer escape or disguise the contradictory character of the modern state. The state is the prime object of economic power. It is captured. Yet on all the matters I have mentioned—the restrictions on excessive resource use, organization to offset inadequate resource use, controls, action to correct systemic inequality, protection of the environment, protection of the consumer—remedial action lies with the state. The fox is powerful in the management of the coop. To this management the chickens must look for redress.

Thus perhaps our greatest question. Is emancipation of the state from the control of the planning system possible? No one knows. And in the absence of knowledge no one certainly will suggest that it will be easy. But there is a gleam of encouragement. As ever circumstances are forcing the pace.

In the United States the recent election was fought, all but exclusively, over issues in which the purposes of the planning system or its major participants diverge from those of the public. The question of defense expenditures is such an issue. That of tax reform is another. The deprivation in housing, mass transportation, health services, city services, is yet another—one that reflects the relative inability of these industries to organize and command resources. The question of a guaranteed income is another such issue. Its effect, as I have noted, is on incomes outside the planning system—on the exploited in the market system, those who are rejected by both. The environment is such an issue—with its conflict between the technostructure's goal of growth and the public concern for its surroundings. Only wage and price control was not an issue in the recent election. That was almost certainly because economists of orthodox tendency on both sides found the prospect too embarrassing to discuss.

I do not mention these issues with any purpose save to show that the questions that emerge when power is made a part of our calculus are present and real. We need hardly remind ourselves that political issues are made not by parties and politicians but by circumstance.

Once power is made part of our system, we will not of course escape the political contention that comes from dealing with issues that are real. This brings me to my last point. I do not plead for partisanship in our economics but for neutrality. But let us be clear as to what is neutral. If the state must be emancipated from economic interest, a neutral economics would not deny the need. This is what economics now

does. It tells the young and susceptible and the old and vulnerable that economic life has no content of power and politics because the firm is safely subordinate to the market and to the state and for this reason it is safely at the command of the consumer and citizen. Such an economics is not neutral. It is the influential and invaluable ally of those whose exercise of power depends on an acquiescent public. If the state is the executive committee of the great corporation and the planning system, it is partly because neoclassical economics is its instrument for neutralizing suspicion that this is so. I have spoken of the emancipation of the state from economic interest. For the economist there can be no doubt as to where this task begins. It is with the emancipation of economic belief.

Short-Run Dynamics in Models of Money and Growth

By DOUGLAS D. PURVIS*

Originating with James Tobin's initial treatment of money as a second asset in the Solow one-sector growth model, the subject of money and growth has received a great deal of attention in the recent literature. Tobin's emphasis on portfolio balance to determine the equilibrium of the model provides a useful framework for the discussion of the development of two opposing "schools of thought" among recent writers on the subject of money and growth. The neoclassical approach follows Tobin in his emphasis on portfolio balance and includes contributions by Miguel Sidrauski and Harry Johnson, among others. A cogent and comprehensive statement of the neoclassical viewpoint can be found in the excellent survey by David Levhari and Don Patinkin. The second approach—the Keynes-Wicksell approach —as expounded by Jerome Stein in particular, and also including contributions by Hugh Rose and Keizo Nagatani, faults the neoclassical model on two basic and related points. They are the implications of the model for the dynamics of price change, and the lack of independent savings and investment decisions.

The neoclassical approach is characterized by the assumption that desired per capita real balances are always held—prices must adjust instantaneously to assure portfolio balance. A given rate of expansion of the nominal money stock combined with the exogenously given rate of population growth serves to determine the equilibrium rate of inflation consistent with asset equilibrium. The division of assets between money and physical capital is thereby determined, and there need be no specification of an independent investment function—all physical savings are instantaneously channelled into capital accumulation, and the desired capital stock is always held.[1]

The long-run properties of the neoclassical model allow for the coexistence of nonzero steady-state inflation and goods market equilibrium by specifying that excess demand for goods causes a departure from the steady-state rate of inflation, but is not a necessary condition for a nonzero inflation rate at any point in time. It is contended that, in a dynamic world, there are two forces operating to drive the price level—excess demand for goods and inflationary expectations. In steady state, excess demand is zero; actual inflation equals expected inflation, not necessarily zero; and the possibility of nonzero steady-

* Queen's University. This paper was written while I was a graduate student at the University of Chicago. My understanding of the issues has been greatly improved by many discussions with Rudiger Dornbusch, Stanley Fischer, and Michael Mussa. I also wish to thank members of workshops at the University of Chicago, University of Rochester, and York University, and to participants in the Chicago Symposium on Trade, Growth, and the Balance of Payments (University of Chicago, December 1970) for helpful comments on an earlier version of this paper. Jerome Stein, George Borts, and an anonymous referee provided very useful comments for which I am most grateful. Of course, I am responsible for any remaining errors. Financial support from the Canada Council is gratefully acknowledged.

[1] A puzzling result of Tobin's initial treatment is that the introduction of money into the barter model lowered the capital intensity and output per capita. I have recently tried to analyze this seemingly paradoxical result elsewhere (see Purvis).

state inflation represents a continuously changing equilibrium price level. However, the assumptions concerning portfolio balance outlined above impose rather implausible restrictions on the short-run behavior of the price level—prices must adjust instantaneously and completely to eliminate any disequilibrium. Hence when monetary disturbances are introduced into the analysis, the neoclassical model is seen to generate undesirable (or, at least, unrealistic) short-run movements in the price level.[2]

Accordingly, the essential features incorporated into the Keynes-Wicksell models are the specification of independent savings and investment decisions, and the explicit representation of a price equation in which prices move only in response to excess demand in the goods market. An immediate unfortunate consequence of such a model is that if monetary policy is such that the steady state is characterized by a nonzero rate of inflation, then there must be perpetual disequilibrium in the goods markets such that the plans of savers or investors, or both, must be frustrated continually. At this point the Keynes-Wicksell proponents need to resort to a *deus ex machina*—the institutionally determined allocation of frustrations—to close the model.

In a recent article, Stein has elucidated the differences between the two approaches, elaborating in particular on this very point of the different foundations of and implications for the dynamics of price change inherent in the two approaches. He apparently accepts the criticism outlined in the above paragraph, and outlines a proposal for reconciling the two approaches in which disequilibrium causes inflation to diverge from its expected value. Unfortunately, this analysis is hindered by a stock flow confusion arising from Stein's treatment of the Keynes-Wicksell model. There he (correctly) uses Walras' Law to relate price changes to the excess *flow* supply of money, but then chooses to treat the special case where a *flow* excess supply of money corresponds to a *stock* excess supply of money in such a manner that prices can be represented to move in response to a *stock* excess supply in the money market.[3] As we shall show below, this seemingly innocuous misspecification gives rise to some unnecessary complications in the analysis.

It is argued here that along with the specification of the determinants of inflation, the mere possibility of stock disequilibrium is in fact the crucial point of departure from the neoclassical scenario; and by explicitly considering the implications of stock disequilibrium on the demand behavior of the asset holders, the neoclassical and Keynes-Wicksell approaches are more easily reconcilable. Further, I hope to show that such considerations lead to the construction of a model which retains the desirable long-run properties of the neoclassical model, but which has more desirable short-run properties than either the neoclassical or Keynes-Wicksell models outlined above. This short-run behavior is derived from explicit analysis of flow equilibrium for assets in a model in which careful attention is given to the development of consistent stock-flow relationships under conditions of possible stock disequilibrium.

[2] That is, the neoclassical model represents a "frictionless" world in perpetual equilibrium. The present paper introduces adjustment costs whereby prices respond to eliminate asset disequilibrium only over time. On this, also see Fischer.

[3] Of course, the two are obviously closely related, but Stein's analysis implies the very restrictive case of a linear homogeneous relationship. Later in the present paper we incorporate a stock-adjustment term into the flow demand, and then Stein's case is only valid when the flow supply of real balances can be assumed constant. This seems most inappropriate for the analysis of short-run price behavior where shocks are induced through changes in the flow supply.

A simple neoclassical model is constructed in Section I, and its dynamics are briefly explained. In Section II adjustment costs are explicitly introduced into the neoclassical model in order to rationalize the possible existence of stock disequilibrium. Given such a disequilibrium, and given the assumed adjustment costs, wealth holders are seen to adjust their asset holdings along an optimal adjustment path which eliminates the stock disequilibrium *over time*. No uncertainty is involved—asset holders are assumed to be able to perceive the adjustment costs correctly and hence form flow demands that are feasible. Thus the adjustment process, or transitional stage, is characterized by flow equilibrium. It is important to note that while this transitional stage is also characterized throughout by stock disequilibrium, it is not correct to consider the analysis of the short-run behavior as "disequilibrium dynamics." It is equilibrium dynamics in the flow sense: given the initial stock disequilibrium, and given the assumed costs of adjusting these stocks, wealth holders adjust asset holdings in a *optimal* manner along an *equilibrium* path. Thus the analysis lends itself to the usual economic approach of considering a constrained optimization procedure giving rise to a set of equilibrium conditions.[4] Long-run equilibrium or steady state is restored when the stock disequilibrium is eliminated. Finally, in Section III, the special case analyzed by Stein is treated briefly, and some concluding comments are offered summarizing the implications of the reconciliation achieved.

I. A Simple Neoclassical Model

For simplicity, we will explore only the case where money is produced costlessly, held only by consumers, and distributed as a government transfer payment independently of existing real balances.[5] Per capita output is given by equation (1) and disposable income which includes changes in the value of existing real balances is given by equation (2):

$$(1)\qquad y = y(k)$$

$$(2)\qquad y_d = y(k) + m(\mu - \Pi)$$

where m is actual real balances per capita, k is the existing capital-labor ratio, μ is the given constant rate of increase in the nominal money stock, and Π is the actual rate of inflation. We assume that the labor force is growing at the constant exogenously given rate n, and that, for now, per capita consumption, c, is a constant fraction, $(1-s)$ of disposable income.[6]

Then, letting D denote the operator d/dt, and denoting physical savings per capita by S_p, we have:

$$(3)\qquad Dk = (y - c) - nk = S_p - nk$$

Portfolio equilibrium is achieved when the stock demand for real balances, given by equation (4), equals the stock supply.

$$(4)\qquad m^d = b(i)\cdot y(k);\quad b' < 0$$

In equation (4), desired per capita real balances are positively related to per capita output,[7] and the coefficient b

[4] The analogy to the stock-adjustment processes which have received a great deal of attention in the recent literature on the theory of investment of the firm is obvious. For example, see J. P. Gould.

[5] The latter assumption is necessary in order to retain the effects of monetary policy on the steady-state capital intensity. See Stein, p. 96.

[6] The limitations of this assumption are well known; however, it will suffice for our purposes except for the following important qualification. In a model incorporating stock disequilibrium, any semblance of maximizing behavior would indicate a savings rate varying with the stock disequilibrium. This is introduced in the savings function given by equation (13) in the text. Of course, a more satisfactory treatment would be a model of full dynamic optimization.

[7] It may be more correct to relate m^d to disposable income, but as the choice is inconsequential to my results, the present analysis is maintained for simplicity and for compliance with most of the literature.

varies inversely with the nominal interest rate i, defined as the sum of the real rate of interest $y'(k)$, plus the expected rate of inflation, Π^e.

$$i = y'(k) + \Pi^e$$

In order to concentrate later on the stock adjustment process, the simplifying but unrealistic assumption is made that Π^e always equals the equilibrium rate of inflation, $\Pi^e = \mu - n$.

Equilibrium, or steady state, occurs when $Dk = 0$, or, equivalently, when per capita physical savings S_p, given by equation (5), equals the investment requirement, nk.

$$(5) \quad \begin{aligned} S_p &= [s - (1 - s)\cdot b\cdot(\mu - \Pi)]y(k) \\ &= \sigma(k, \Pi)\cdot y(k) \end{aligned}$$

where $\sigma(k, \Pi)$ is the physical savings ratio; $\sigma_k < 0$, $\sigma_\Pi > 0$.

Following Sidrauski we set $S_p = nk$ and solve for equilibrium real balances, given by equation (6):

$$(6) \qquad m^* = \frac{sy(k^*) - nk^*}{(1 - s)n} = m(k^*)$$

where the asterisks denote equilibrium or steady-state values. Equation (6), plotted as the m^* curve in Figure 1, represents the (long-run) goods market equilibrium locus along which the per capita capital stock is constant. Above m^* there will be excess demand in the goods market and k will be falling, and conversely below m^*.

In Figure 1, $OR(\Pi_0)$ plots equation (4) for a given value of $\Pi^e = \Pi_0$; hence $OR(\Pi_0)$ is the locus of portfolio equilibrium along which $m(\equiv m^d)$ would be constant. Above and to the left of OR, m would be falling and conversely below OR. Of course, as emphasized above, the neoclassical model is characterized by perpetual asset equilibrium so these latter adjustments take place instantaneously via changes in the price level and all adjustment takes place

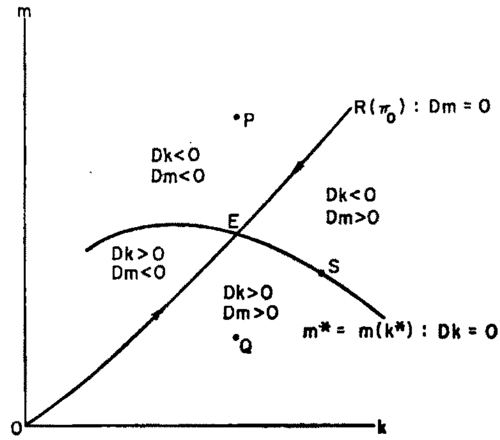


FIGURE 1

along $OR(\Pi_0)$ in Figure 1. Steady state, of course, attains at E.

A once-for-all increase in the nominal money supply would cause the economy to move momentarily to a position such as P, giving rise to an instantaneous proportionate increase in the price level causing it to return instantly to E. An increase in the rate of expansion of the nominal money stock would increase the equilibrium and expected rate of inflation causing OR to rotate clockwise; say now passing through points Q and S. Desired real balances would fall, hence prices would rise immediately to move the economy initially to a point such as Q. Then it would move along the new OR curve towards the new equilibrium position S.

The price dynamics of the neoclassical model can be seen by differentiating equation (4) with respect to time, and solving for Π, yielding:

$$(7) \qquad \Pi = \mu - n - \frac{B(k, \Pi^e)}{m}\cdot Dk$$

where $B(k, \Pi^e)$ is defined as $\partial m^d/\partial k$, i.e.,

$$B(k, \Pi^e) = [y(k)\cdot b'(i)\cdot y''(k) + b(i)\cdot y'(k)]$$

which is positive under usual assumptions on $y(k)$.

In the steady state, $Dk=0$ by definition, and hence equation (7) has the desirable steady-state solution $\Pi=\mu-n$. Further, from equation (7) it is found that in order for Π to exceed its steady-state value $\mu-n$, capital must be decumulating. That is, in terms of Figure 1, the section of *OR* northeast of *E* corresponds to a rate of inflation in excess of the steady-state rate, $\mu-n$ (i.e., real balances are falling), and conversely for the segment of *OR* southwest of *E*.

Before going on to consider the reconciliation of this model with the Keynes-Wicksell criticisms outlined above, it is perhaps worthwhile discussing briefly the attempt by Sidrauski to incorporate more reasonable short-run behavior into the neoclassical model by introducing adaptive expectations into the analysis. Since desired real balances are functionally dependent on the expected rate of inflation, gradual adjustment in expectations allows actual and desired real balances to remain equal; and at the same time, actual real balances can adjust more slowly towards their long-run equilibrium level following an exogenous monetary disturbance. Below the short-run behavior of our model is compared with that achieved by Sidrauski.

II. A Model With Stock Disequilibrium: A Proposed Neoclassical Variant

We wish now to relax the neoclassical assumption of perpetual stock equilibrium, in the sense that we no longer wish to treat m^d given by equation (4) as being identically equal to actual per capita real balances m. Such divergence between actual and desired real balances must ultimately derive from the existence of transactions costs in asset markets. In this section, it is assumed that there exist rising marginal costs to the rate of change of holdings of capital.[8] Then, as the wealth holder has only two asset forms in which he can hold wealth, and will choose to equalize own rates of return at each point in time, it is plausible to consider him at some point in time holding a stock of real balances different from his long-run desired stock. That is, we no longer constrain the price level to adjust instantaneously to eliminate any stock disequilibrium in the money market.

However, any stock disequilibrium will be eliminated over time as the wealth holder adjusts in an optimal manner. That is, the stock excess demand for real balances will affect the flow demand for real balances via some stock adjustment mechanism. As a first approximation, we postulate the following flow demand for real balances:

$$f^d = nm^d + B(k, \Pi^e) \cdot Dk - \alpha \cdot \bar{\bar{m}} \tag{8}$$

where the first term on the right-hand side of equation (8) is the steady-state flow demand, and the second term is the adjustment in desired real balances for changes in capital intensity as the economy moves towards the steady state.[9] The third term is the stock adjustment component of flow demand where $\bar{\bar{m}}$ is the stock excess supply of real balances $m-m^d$; and where α, the "speed of adjustment coefficient," has dimension time^{-1}. In order to simplify the

[8] This is obviously related to the Penrose effect in the theory of investment. See Hirofumi Uzawa and the references cited there. In the present case, the costs of changing wealth positions include, of course, consumption foregone.

[9] It seems unreasonable that wealth holders would demonstrate the kind of price expectations specified and still express demand functions in terms of current variables only. It would seem more appropriate to have them demonstrate similar degrees of sophistication in all markets. For example, the expectations function specified would be more consistent if demands were in terms of permanent incomes, while the present demand functions would be more consistent if combined with expectations $\Pi^*=\Pi$ (t). However, for present purposes we follow the case set out in the text. Although we refer to nm^d as the steady-state component, it differs from its steady-state value when the economy is out of steady state, i.e., when $m^d \neq m^*$. $B(k, \Pi^e)Dk$ represents the movement along the *OR* curve of Figure 1.

analysis while still emphasizing the stock-adjustment mechanism, we will treat α as a constant.[10]

The concept of the stock demand for real balances seems to warrant further comment at this point. The quantity m^d given by equation (4) defines, for given k and given Π^e, the stock that the asset holder would wish to be holding in the absence of any costs involved in adjusting his actual stock to that level, and m^d then can be regarded as the long-run desired stock of real balances. However, at any point in time there exists the distinct concept of the stock that the asset holder wishes to hold *at that instant*, given the existing stock (which may differ from the quantity m^d), and given the costs involved in changing the level of that existing stock. This latter concept can be regarded as the short-run (or instantaneous) desired stock of real balances, m^s.

While this distinction is useful in sorting out the concept of the stock demand for real balances, it is even more useful in clarifying the nature of the role played by the flow demand for real balances.[11] The long-run stock demand, m^d, except insofar as expectations are effected by asset flows, is defined independently of those flows. However, the short-run stock demand, m^s, and the flow demand are closely tied in the following way. By the very nature of the term $\alpha \cdot \bar{\bar{m}}$ in the flow demand given by equation (8), if real balances are growing at the desired rate then the asset holder is in short-run stock equilibrium. This is reconciled with the existence of stock disequilibrium in the long-run sense by the fact that the disequilibrium is being eliminated at the desired rate, and hence the wealth holder is, at that instant and in this limited sense, "happy" with his present stock of real balances. That is, m^s is the "effective" stock demand at any instant when the constraint imposed by the adjustment costs is taken into consideration; and the maintenance of flow equilibrium assures that m^s will identically equal actual m at every point in time. Then f^d will also equal the time derivative of $m^s (\equiv m)$.

Flow supply, f^s is given by equation (9), and the excess flow supply of real balances, $\bar{\bar{f}}$, by the difference $f^s - f^d$, in equation (10):

$$f^s = m(\mu - \Pi) \tag{9}$$

$$\bar{\bar{f}} = m(\mu - \Pi) - nm^d - B(k, \Pi^e) \cdot Dk + \alpha \bar{\bar{m}} \tag{10}$$

Now, although there may be stock disequilibrium at any point in time ($m^d \neq m$), wealth holders are able to add to their existing real balances at the desired rate—again, this is the nature of the term $\alpha \cdot \bar{\bar{m}}$ in equation (8). Then $\bar{\bar{f}}$ identically equals zero, and we can solve equation (10) for Π:

$$\Pi = \mu - n + \frac{\bar{\bar{m}}}{m} \cdot (n + \alpha) - \frac{B(k, \Pi^e)}{m} \cdot Dk \tag{11}$$

In the steady state, $\bar{\bar{m}} = Dk = 0$, so equation (11) has the desired steady-state solution, $\Pi = \mu - n$. For Π to exceed its steady-state value, $\bar{\bar{m}} \cdot (n + \alpha)$ must exceed $B(k, \Pi^e) \cdot Dk$. Now, contrary to the simple neoclassical model, it is possible for capital to be accumulating while the rate of inflation exceeds its steady-state value *if* there is a large enough excess stock supply of real balances.

If we define z as the excess of Π over its steady-state value, from equation (11) we

[10] A more complete analysis would undertake a full intertemporal dynamic optimization to determine the exact characteristics of the adjustment process—for an example of such an analysis in the theory of investment of the firm, see Gould.

[11] In terms of the language of the recent literature on the general theory of disequilibrium (see, for example, Herschell Grossman), m^d and m^s correspond closely to the concepts of "notional" and "effective" demand, respectively.

see that Dk is related to $\overline{\overline{m}}$ according to:

$$(12) \quad Dk = -\frac{1}{B(k, \Pi^e)} \cdot [zm - \overline{\overline{m}}(n + \alpha)]$$

Equation (12) is the flow equilibrium condition in the money market. For any given value of z, Dk is positively related to $\overline{\overline{m}}$ indicating the portfolio adjustment entailing dishoarding of real balances, and accumulation of physical capital. This relationship is plotted in Figure 2 where we get a family of positively sloped curves mm, each corresponding to different values of Π (or, equivalently, of z). For any point in $(Dk, \overline{\overline{m}})$ space there exists a value of Π consistent with flow equilibrium in the money market.

However, Dk must, in fact, move in accordance with equation (3)—the flow equilibrium condition in the goods market—except that we are no longer free to interpret that savings rate as a constant (compare fn. 6). To proceed, we need to explicitly introduce the long-run desired capital stock k^d. Of course, k^d cannot be specified independently of m^d since in the steady state when the long-run desired stocks are being held, the asset demands m^d and k^d must satisfy the wealth constraint, $w = m^d + k^d$. However, when we allow for stock disequilibrium, it is possible at any point in time to have an excess demand (or supply) for wealth in the sense that k^d plus m^d exceeds (falls short of) k plus m.[12] Then we wish to postulate the following behavior of the savings ratio:

$$(13) \qquad s = s(\overline{\overline{m}}, \overline{\overline{k}}); \quad s_1 < 0, s_2 < 0$$

where $\overline{\overline{k}}$ is the excess of actual k over k^d. The signs of the partial derivatives arise from the belief that an excess stock supply of either asset will induce people to consume a larger proportion of any given income, and hence the savings rate falls. We could have considered the simpler case where s depends only on the sum $\overline{\overline{m}} + \overline{\overline{k}}$, but the present analysis allows for the more general behavioral assumption that, although the two excess demands are obviously not independent, the asset holder may wish to adjust one at a different rate than the other. Of course, both versions yield the same steady-state solutions.

Then equation (3) can be rewritten as

$$(3') \qquad \begin{aligned} Dk &= \phi(\overline{\overline{m}}, \overline{\overline{k}}, \Pi); \\ \phi_1 &= s_1[y(k) + m(\mu - \Pi)] < 0 \\ \phi_2 &= s_2[y(k) + m(\mu - \Pi)] \\ &\quad + (sy' - n) \gtrless 0 \\ \phi_3 &= (1 - s) \cdot m > 0 \end{aligned}$$

Although the sign of ϕ_2 is theoretically ambiguous, it will be negative for all but very large negative values of $\overline{\overline{k}}$, and we shall treat ϕ_2 as negative throughout the analysis. Equation (3′), for $k^* = k$ and $\Pi = \Pi^e$ is plotted in Figure 2 as cc.[13] When we recognize that goods market equilibrium implies flow equilibrium in the money market, we can draw a goods market equilibrium curve for $k = k^*$ by allowing for the required change in Π. This is seen as $c'c'$ in Figure 2, which is flatter than cc due to the sign of ϕ_3. An increase

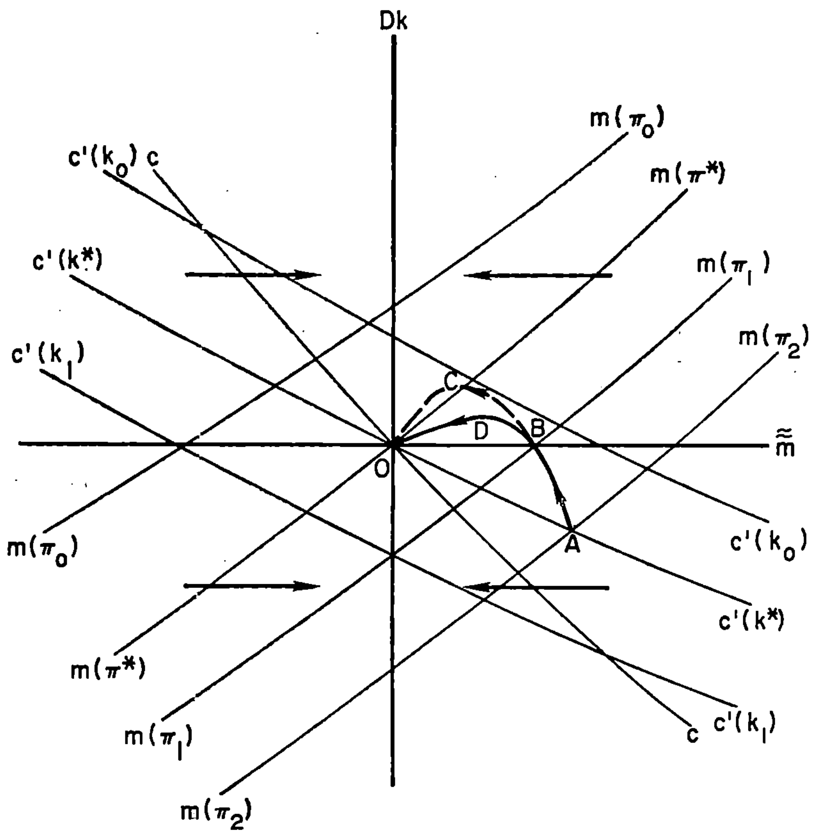
[12] In the text, w is interpreted as actual wealth, equals desired wealth in the steady state. Out of the steady state, it is $k^s + m^s$ that is constrained by actual wealth, $w = k + m$; where the interpretation of k^s is analogous to m^s. However, by the flow equilibrium postulate, $k^s - k = m^s - m = 0$, so that not only do the "short-run excess demands" sum to zero, but each individual short-run excess demand equals zero. Consideration of k^d demonstrates why the two Keynes-Wicksell criticisms of the neoclassical model cited in the second paragraph of the present paper are related. The neoclassical assumption of perpetual asset equilibrium extends, of course, to k^d; hence there is no need to also consider explicitly an investment function.

[13] The diagrammatic framework used here is not well suited for dynamic analysis—it would be more useful to work in state variable space. However, Figure 2 clearly sets out what is going on in the model, and how the portfolio adjustment and goods market equilibrium interact to determine Π and Dk.

in the capital stock would shift $c'c'$ down, and conversely for a fall in the capital intensity. Thus, again we get a family of curves, this time with negative slope each one plotting the equilibrium combinations of Dk and $\bar{\bar{m}}$ for a given capital intensity.

At any point in time m, p, k, μ, Π^e, and y are all given, and flow equilibrium determines Π—and hence i—and Dk. In terms of Figure 2, this can be seen as follows. From given k, we can determine which $c'c'$ curve we are on. From given m, k, and Π^e we also know $\bar{\bar{m}}$, and hence we can determine where we are on the $c'c'$ curve. We can then read Dk off the vertical axis and determine Π by the mm curve passing through the point on the $c'c'$ curve. As k and Π change through time, the time path of the economy can be determined by the locus of the intersections of the appropriate mm and $c'c'$ curves. Steady state in the economy occurs, of course, at the origin in Figure 2, where $Dk=\bar{\bar{m}}=0$.

Now consider at time t_0 a perturbation of a steady state by a once-for-all increase in the rate of expansion of the nominal money stock from μ_0 to μ_1. The immediate effect of an increase in μ is to create an excess stock supply of money: by our static expectations hypothesis the demand for real balances falls instantaneously while the actual stock rises initially (i.e., before there is any effect on



(where $\pi_2 > \pi_1 > \pi^* > \pi_0$ and $k_1 > k^* > k_0$)

FIGURE 2

the price level). At t_0, $\bar{\bar{m}}$ will be positive and there will be an excess demand for goods as desired consumption rises and wealth holders try to dishoard by entering the goods market. This excess demand causes the rate of inflation to rise and the economy moves to a more southeasterly *mm* curve; initially the capital stock is given and we remain on the original $c'c'$ curve. The economy then has moved to point A in Figure 2 where Π has been bid up to Π_2 and Dk is less than zero.

At A, $\bar{\bar{m}}$ is positive, and due to our static expectations hypothesis, unambiguously falling.[14] On the other hand, $\bar{\bar{k}}$ is negative and falling ($Dk \leq 0$), causing $c'c'$ to shift northeasterly. Then, in Figure 2, the economy is moving northwesterly from A, and Π is falling. Our expectations hypothesis is sufficient to require that $\bar{\bar{m}}$ fall asymptotically to zero. The new steady state will be characterized by a higher capital intensity and hence the adjustment path will be constrained to satisfy

$$\int_{\tau A}^{T_0} Dk\mathrm{d}t = \theta$$

where θ is the change in the equilibrium capital intensity derived from the comparative dynamics of the model.[15] Two possible adjustment paths $ABCO$ and $ABDO$ are plotted; k, and hence m^d, attain their minimum values at B, then rise directly to their respective new long-run equilibrium values. Along $ABDO$, m and Π fall directly to their respective long-run equilibrium values, whereas along $ABCO$, both m and Π would overshoot and then approach their new equilibrium values from below.

Along the segment AB, the dishoarding is reducing $\bar{\bar{m}}$, but increasing the absolute value of $\bar{\bar{k}}$ (negative); both effects serving to increase the savings rate, and hence increase the share of current output available for capital accumulation. Northwest of B, capital accumulation becomes positive and $\bar{\bar{k}}$ rises; $\bar{\bar{m}}$ continues to fall and both effects are now working towards the restoration of portfolio equilibrium. Figure 3 plots representative time paths of the variables for the two alternative adjustment paths, where the starred variables represent the new equilibrium values corresponding to μ_1.[16] In terms of Figure 1, the economy moves initially to P, and then adjusts gradually, first in a southwesterly direction (capital intensity falling) until it crosses m^* after which it moves southeasterly to the new equilibrium position S.

It is useful to compare the behavior of the capital stock in this model to that obtained in Sidrauski's analysis in which long-run desired balances are always held, but expectations are adaptive. In Sidrauski's model, an increase in the rate of monetary expansion causes the capital stock to initially fall, and then to rise to its new steady-state level. Also, in that model, the increased real balances initially cause an increase in consumption, but in this case it is due to the fact that the increased balances are treated initially as an income transfer since the new higher equi-

[14] To see this, consider $D\bar{\bar{m}} = m(\mu - n - \Pi) - B(k, \Pi^e) \cdot Dk$, so for $D\bar{\bar{m}} < 0$, we require $\Pi > \mu - n - (B/m) \cdot Dk$, which from equation (11) occurs whenever $m > 0$. Hence we can draw the heavy black horizontal arrows in Figure 2.

[15] Our model retains the neoclassical equilibrium properties. See Levhari and Patinkin for a thorough treatment of the comparative dynamics propositions of the model. If we had considered the simple case of a once-for-all increase in the nominal money stock, we would again have an initial excess supply of real balances, and the resulting adjustment path would be similar to that considered in the text, constrained so that

$$\int_{\tau_A}^{T_0} Dk\mathrm{d}t = 0$$

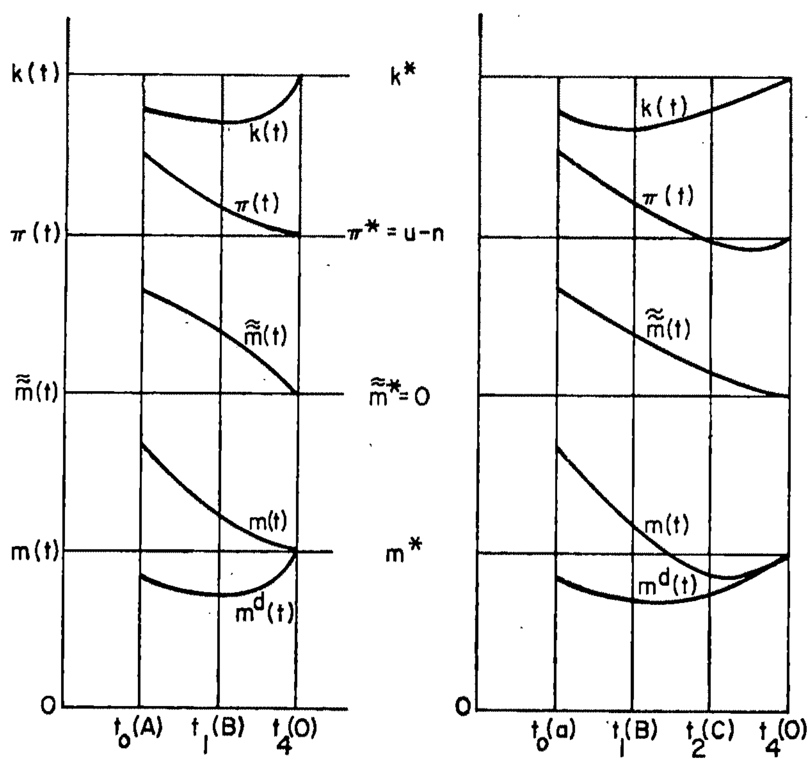
[16] The long-run effect on m^d is uncertain; the nominal rate of interest may rise or fall and hence, so may m^d (see Levhari-Patinkin, pp. 731–32). Figure 3 is drawn on the assumption that the steady-state value of $m^d(m^*)$ rises with μ.

librium rate of inflation is initially not anticipated. Hence, in a sense, there wealth holders also tend to consume out of their "excess stock supply of real balances." Only after a period of time sufficient for the increased rate of inflation to become more fully anticipated do they adjust their portfolios in favor of physical capital. If that model had our static expectations, the capital stock would rise immediately as the new steady-state inflation rate would be fully anticipated immediately.

In our present model, the actions of the monetary authority create a stock disequilibrium and the wealth holders then proceed to inject it into the economy over time by consuming out of their excess stock supply of real balances. The analogy to an economy with no adjustment costs but in which price expectations are sluggish, or in which the rate of expansion of the money supply is varied over time, is immediate.

Similar experiments such as money destruction, or national disasters which destroy part of the capital stock could also be treated, and the model could be easily extended to include such considerations as adaptive expectations and inside money.

While the present analysis still requires "blips" in the price level in response to monetary shocks, that seems to be a consequence of analyzing discrete policy jumps in a continuous time model. Our neoclassical variant does, however, appear capable of handling nonsteady-state behavior in a richer manner than the simple



3A ADJUSTMENT PATH ABDO

3B ADJUSTMENT PATH ABCO

FIGURE 3

neoclassical model which had virtually no explicit analysis of asset flows. The crucial feature of our model which yields this richer analysis is the explicit treatment given to the possibility of stock disequilibrium, and the ensuing analysis of the implications of such stock disequilibrium for asset flows and resulting interactions with the commodity market.

III. Concluding Comments

Finally consider the case suggested by Stein which might be construed as implying the following price equation:[17]

$$\begin{aligned}\Pi &= \mu - n + h \cdot \bar{\bar{f}} \\ (14) \qquad &= \mu - n + \frac{h}{1 + hm}\,[\bar{\bar{m}}(n + \alpha) \\ &\quad - B(k, \Pi^e) \cdot Dk]\end{aligned}$$

Again, in the steady state, $\bar{\bar{f}} = \bar{\bar{m}} = Dk = 0$, so equation (14) has the desired steady-state solution $\Pi = \mu - n$; and Dk can be related to $\bar{\bar{m}}$ and z by equation (15):

$$(15) \qquad Dk = -\frac{1}{B(k, \Pi^e)} \cdot \left[z\left(\frac{1}{h} + m\right) - \bar{\bar{m}}(n + \alpha) \right],$$

which is similar to equation (12). We also have the same conditions in the goods market, except we are not here constrained to flow equilibrium, and hence would conduct the analysis in terms of the cc curves, and not the $c'c'$ curves.

[17] Stein's analysis implies $\bar{\bar{f}} = q \cdot \bar{\bar{m}}$. Solving for q from equation (8):

$$\begin{aligned} q &= n - z\frac{m}{\bar{\bar{m}}} - \frac{B(k, \Pi^e)}{m} \cdot Dk + \alpha \\ &= q(\mu, k, Dk), \end{aligned}$$

so it is really not consistent with our formulation of the money flow demand given by equation (8) to treat q as a constant. Note that the limits of equation (14) and (15) as $h \to \infty$ are (11) and (12); this gives us the most restrictive case of all with only steady-state behavior possible, i.e., in Figure 1 the economy is restricted not only to positions along OR, but simply to be at E.

Thus, either equations (11) and (12), or equations (14) and (15) might be used to analyze nonsteady-state behavior. The first set represents essentially the neoclassical view wherein the price level is essentially driven by the money market, but in which costs of adjustment in asset markets which give rise to stock disequilibria phenomena are allowed for. The latter set is perhaps more in the spirit of the Keynes-Wicksell paradigm, inasmuch as nonsteady-state behavior in the price level requires nonzero excess flow demand for real balances, and therefore nonzero excess demand in the goods market. Then this latter model still requires some arbitrary method of allocating frustrations. A second problem arising in this latter model is that, just as in the original Keynes-Wicksell models, no forces operating to rationalize stock disequilibrium were introduced, and nothing is inherent in the model to prevent the achievement of flow equilibrium. This is particularly disturbing when our flow money demand equation (8) is introduced as we do here to obtain equation (14).

It therefore seems worthwhile treating in more detail the fact that in our neoclassical variant there need be no arbitrary allocation of frustrations. In terms of the demand relationships "effective" at a point in time, there need be no frustrations for there is perpetual flow equilibrium. Wealth holders are frustrated only in the sense that they do not instantaneously achieve their desired long-run wealth position. However, the wealth holders do make plans to adjust their wealth position in an optimal manner, and there is nothing inherent in the model to prevent the attainment of these plans.

It is hoped that the present paper contributes to the reconciliation sought by Stein in the concluding section of his paper. There he states, "The steady state must be the asymptotic solution of the short-run

dynamic model: It cannot be brought in as a *deus ex machina*" (p. 104). I believe that the neoclassical variant introduced in Section II of the present paper meets this criteria while maintaining the clearly desirable steady-state features of the neoclassical model, and introducing short-run characteristics which are more appealing and meaningful from the viewpoint of contemporary economic thought. Of course, as a description of short-run macro-economic behavior the present model is incomplete. A complete model would, at the very least, need to incorporate the effects of uncertainty and expectational disequilibrium into the analysis and allow for the existence of unemployment.

An Analysis of Cooperation and Learning in a Duopoly Context

By RICHARD M. CYERT AND MORRIS H. DEGROOT*

A number of recent papers have introduced the notion of treating duopoly as a multiperiod maximization problem (see Cyert and DeGroot (1970a), and James Friedman (1968)). Previously, duopoly was viewed simply as a one-period maximization problem or as some minor variation of the latter. Recent work has shown that through the utilization of the concept of backward induction, models can be developed free from the earlier restrictions of limited period analysis.[1]

In all of these models, certain fixed assumptions about the behavior of the two firms are made, and optimal strategies are then developed for the firms in a multiperiod problem based on these fixed behavioral assumptions. In a problem with a large number of periods, an equilibrium position is ultimately established. There are no models currently in existence that enable the firms to change their behavioral assumptions and their strategies during the process of reaching an equilibrium position.

In this paper we develop a model in which the firms move in a rational fashion, from a path leading to a noncooperative equilibrium to paths leading to equilibria defined by various degrees of cooperation and ultimately to the cooperative (collusive) solution. In the process of constructing this model, we will introduce the notions of a coefficient of cooperation and of mutually optimal reaction functions. We will derive such mutually optimal reaction functions for various coefficients of cooperation. We will also utilize the concept of Bayesian learning contained in previous papers (see Cyert and DeGroot (1970b), (1971)).

I. Coefficient of Cooperation

Consider a duopoly problem in which the demand function in any given period is $p=f(q, r)$, where q is the output of firm 1 in that period and r is the output of firm 2. If $c_1(q)$ denotes the cost function of firm 1 in each period and $c_2(r)$ denotes the cost function of firm 2, then the profit π_i of firm i $(i=1, 2)$ will be

$$\pi_1(q, r) = qf(q, r) - c_1(q),$$
$$\pi_2(q, r) = rf(q, r) - c_2(r)$$

Thus in a process with n periods in which q_j and r_j denote the outputs in period j $(j=1, \ldots, n)$, the total profit of firm i over the n periods will be

$$\sum_{j=1}^{n} \pi_i(q_j, r_j)$$

The basic goal of each firm is to maximize its total profit. It is well known that this total profit will be higher for both firms

We are indebted to James Friedman, Martin Geisel, Robert Lucas, Edward Prescott, Nancy Schwartz, and Oliver Williamson for their helpful comments on an earlier version of this paper. We also benefited greatly from the coments of the members of the NBER Seminar on Bayesian Inference in Econometrics held in Pittsburgh in May 1971.

[1] Duopoly is a particular type of nonzero sum, two-person game which is related to, but distinct from, the type known as the Prisoner's Dilemma. Robert Luce and Howard Raiffa (pp. 97–102) have discussed a multiperiod analysis of the Prisoner's Dilemma, and F. Trenery Dolbear et al. (1968, 1969) have pointed out the connections between duopoly and the Prisoner's Dilemma.

when they cooperate with each other than it will be when each firm attempts to maximize its own profit without regard to its rival. We propose, therefore, to introduce a utility function for each firm that will encompass the degree of cooperation the firm is prepared to demonstrate toward its rival.

We shall assume that there exists a constant $\gamma (0 \leq \gamma \leq 1)$ such that firm 1 desires to maximize the sum

$$(1) \quad V_1 = \sum_{j=1}^{n} [\pi_1(q_j, r_j) + \gamma \pi_2(q_j, r_j)]$$

In other words, it is assumed that V_1 represents the utility function for firm 1. If $\gamma = 0$, then the sum in (1) is simply the total profit of firm 1 over the n periods. However, if $\gamma \neq 0$, then the sum in (1) is a linear combination of the total profit of firm 1 and that of firm 2. The number γ will be called the *coefficient of cooperation* of firm 1. If $0 < \gamma < 1$, firm 1 is interested in cooperating with firm 2 and desires to maximize its own total profits plus a fraction of the profits of firm 2. If $\gamma = 1$, firm 1 is interested in cooperating with firm 2 to the extent of desiring simply to maximize the total profits of the two firms.[2] Although values of γ outside the interval $0 \leq \gamma \leq 1$ are conceptually possible, such values do not seem to be of practical interest and will not be considered further here.

Similarly, we shall assume that there also exists a constant $\delta (0 \leq \delta \leq 1)$ such that firm 2 desires to maximize a utility function V_2 of the following form:

$$(2) \quad V_2 = \sum_{j=1}^{n} [\pi_2(q_j, r_j) + \delta \pi_1(q_j, r_j)]$$

Thus, δ is the coefficient of cooperation of firm 2.

[2] Friedman (1962) refers to a similar function and credits G. Feeney with suggesting it. However, Friedman does not make the same use of the concept as has been done in this paper, nor has Feeney to the best of our knowledge.

It should be emphasized that in the theory to be presented here, there is a rational reason why each firm attempts to maximize a linear combination such as V_1 or V_2 rather than simply trying to maximize its own profits. The firms recognize that for certain pairs of positive values of γ and δ, their profits will actually be larger when they try to maximize V_1 and V_2 than when each firm tries to maximize its own profits directly. We have called V_1 and V_2 the utility functions of the firms because they choose their outputs in order to maximize these functions. This terminology is slightly inappropriate, however, since the firms ultimately evaluate the usefulness of given coefficients γ and δ, not in terms of how large the values of V_1 and V_2 are, but in terms of how large their individual profits are.

II. Mutually Optimal Reaction Functions

Ignoring the values of the coefficients of cooperation for the moment, we define two reaction functions to be mutually optimal if the intersection point of the two reaction functions is also the point of maximum profit for each firm relative to the reaction function of the rival. This concept can be made clearer by looking at the traditional Cournot model where the reaction functions are not mutually optimal. If firm 1 knows that firm 2 is using the Cournot assumptions, then firm 1 can use this information to develop a new reaction function that will intersect the reaction function of firm 2 at a point that is more profitable for firm 1 (see R. G. D. Allen, pp. 345–47). On the other hand, two reaction functions, one vertical and one horizontal that intersect at the Cournot equilibrium point are mutually optimal. With this preface we undertake a more complete definition and analysis.

Consider now a duopoly problem in which the number of periods n is large. We shall assume that the two firms choose

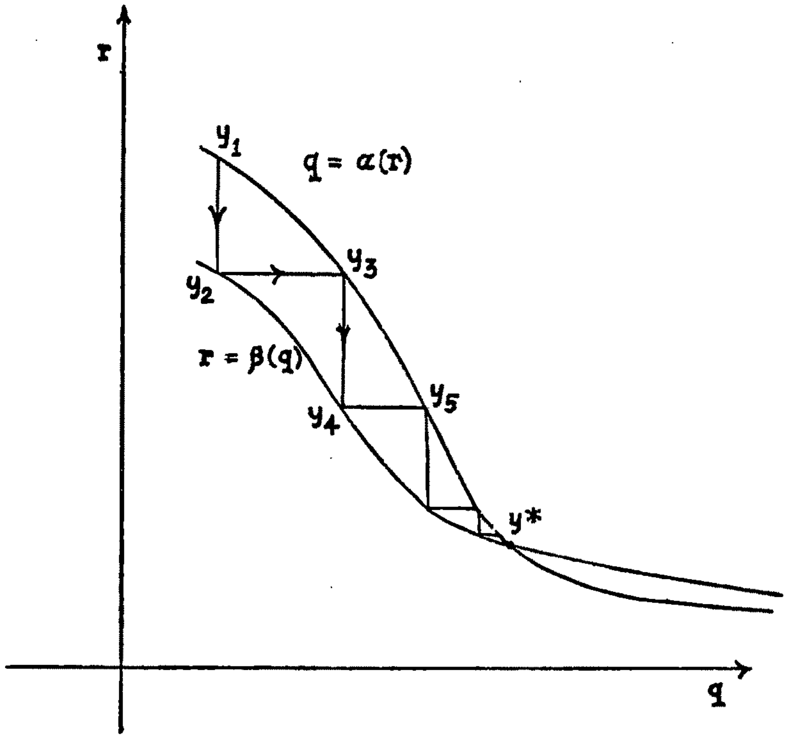

FIGURE 1

their outputs in alternating periods, that firm 1 chooses its output q according to a reaction function $q=\alpha(r)$, and that firm 2 chooses its output r according to a reaction function $r=\beta(q)$. In other words, if firm 2 has just chosen its output in a given period to be r_0, then firm 1 will choose its output in the *next* period to be $q_1=\alpha(r_0)$ while firm 2 holds its output at r_0. In the following period, firm 2 will then choose its output to be $r_2=\beta(q_1)$ while firm 1 holds its output at q_1. The choices continue to be made in this alternating fashion through successive periods.

If the curves $q=\alpha(r)$ and $r=\beta(q)$ intersect at the point $y^*=(q^*, r^*)$, then as indicated in Figure 1, the sequence of successive points

$$y_1 = (q_1, r_0), \quad y_2 = (q_1, r_2),$$
$$y_3 = (q_3, r_2), \quad y_4 = (q_3, r_4), \ldots$$

will typically converge to the point y^*. This convergence to the point of intersection y^* will take place for any reaction functions α and β satisfying the following three properties:[3]

1. Both the curves $q=\alpha(r)$ and $r=\beta(q)$ are decreasing (or nonincreasing).

2. The curve $q=\alpha(r)$ lies above the curve $r=\beta(q)$ for all points (q, r) such that $q<q^*$.

3. The curve $q=\alpha(r)$ lies below the curve $r=\beta(q)$ for all points (q, r) such that $q>q^*$.

Thus, under these conditions, if the two firms repeatedly use the reaction functions $q=\alpha(r)$ and $r=\beta(q)$, their outputs will

[3] These conditions should be familiar to the reader since they are analogous to the constraints on the slopes of the marginal revenue and marginal cost curves in standard competitive theory (see Paul Samuelson, pp. 57–89).

converge to q^* and r^*, regardless of the initial outputs at which the process starts.

Suppose now that the coefficients of cooperation of firms 1 and 2 are γ and δ, respectively, and that each firm knows the rival's cost and reaction functions. In any given period, firm 1 knows that corresponding to any value that it chooses for its output q, firm 2 will react in the next period by choosing the value $r=\beta(q)$. The profits of firms 1 and 2 will then be:

$$\pi_1[q, \beta(q)] = qf[q, \beta(q)] - c_1(q)$$

and

$$\pi_2[q, \beta(q)] = \beta(q)f[q, \beta(q)] - c_2[\beta(q)]$$

Since the coefficient of cooperation of firm 1 is γ, firm 1 is interested in maximizing the value of the utility

$$P_1 = \pi_1[q, \beta(q)] + \gamma\pi_2[q, \beta(q)] \tag{3}$$

Suppose that this utility is maximized at the value $q=q_M$. Because of the convergence which we have described, we know that in the long run, the output of firm 1 will be close to the value $q=q^*$ in every period. It follows, therefore, that from the point of view of firm 1, the most desirable value of q^* is $q^*=q_M$.

For this reason, we shall say that the reaction function $q=\alpha(r)$ of firm 1 *is optimal against* the reaction function $r=\beta(q)$ of firm 2 if $q^*=q_M$. In other words, the reaction function $q=\alpha(r)$ of firm 1 is optimal against the reaction function $r=\beta(q)$ of firm 2 if the point of intersection (q^*, r^*) of the two reaction functions, toward which the outputs of the two firms converge, is also the point on the curve $r=\beta(q)$ at which the utility P_1 of firm 1 is a maximum.

Similarly, for any choice of output r by firm 2 the reaction of firm 1 will be $q=\alpha(r)$ and the profits of the two firms will be $\pi_1[\alpha(r), r]$ and $\pi_2[\alpha(r), r]$. The utility function of firm 2 is

$$P_2 = \pi_2[\alpha(r), r] + \delta\pi_1[\alpha(r), r] \tag{4}$$

and we shall let r_M denote the value of r for which this utility is maximized. Then we say that the reaction function $r=\beta(q)$ of firm 2 is optimal against the reaction function $q=\alpha(r)$ of firm 1 if $r^*=r_M$.

Finally, we say that the two reaction functions are mutually optimal if both $q_M=q^*$ and $r_M=r^*$. In other words, the two reaction functions are mutually optimal if the preferred position of firm 1 along the curve $r=\beta(q)$ is at the point (q^*, r^*) and the preferred position of firm 2 along the curve $q=\alpha(r)$ is also at the point (q^*, r^*). It should be emphasized that the coefficients of cooperation γ and δ are assumed to have given values in this definition and that two reaction functions are considered to be mutually optimal *relative to the given values* of γ *and* δ.

When the two reaction functions are mutually optimal, neither firm will desire to change the point of intersection toward which the outputs are converging by changing its own reaction function as long as the rival firm does not change.

III. Linear Reaction Functions

We shall now apply these concepts to the special but important case in which the demand function is linear and the cost functions of both firms are 0. As described in our previous paper, we can assume without loss of generality that the demand function is of the form $F(q, r)=1-q-r$,[4] so that the profit functions for the firms are

$$\begin{aligned} \pi_1(q, r) &= q - q^2 - qr \\ \pi_2(q, r) &= r - qr - r^2 \end{aligned} \tag{5}$$

Suppose also that both the reaction function $q=\alpha(r)$ of firm 1 and the reaction function $r=\beta(q)$ of firm 2 are linear functions specified as follows:

[4] For simplicity we have not constrained $(q+r)$ to be less than 1 in this form. Thus it is possible to get negative outputs as in Table 2. A negative output stemming from the manipulation of the model has no economic significance.

$$\alpha(r) = T_1 + U_1 r, \tag{6}$$
$$\beta(q) = T_2 + U_2 q,$$

where $|U_i| < 1$ for $i = 1, 2$. Finally, assume that the coefficient of cooperation of firm 1 is γ and that of firm 2 is δ.

For $0 \leq \gamma \leq 1$, the value q_M that maximizes the utility P_1 of firm 1, as given by equation (3), can now be found by elementary differentiation to be

$$q_M = \frac{1 - T_2 + \gamma(U_2 - T_2 - 2T_2U_2)}{2(1 + \gamma U_2)(1 + U_2)} \tag{7}$$

Similarly, for $0 \leq \delta \leq 1$, the value r_M that maximizes the utility P_2 of firm 2, as given by equation (4) will be

$$r_M = \frac{1 - T_1 + \delta(U_1 - T_1 - 2T_1U_1)}{2(1 + \delta U_1)(1 + U_1)} \tag{8}$$

Furthermore, the coordinates of the point of intersection of the reaction functions specified by (6) are

$$q^* = \frac{T_1 + T_2U_1}{1 - U_1U_2} \tag{9}$$

and

$$r^* = \frac{T_2 + T_1U_2}{1 - U_1U_2} \tag{10}$$

The reaction functions specified by (6) will be mutually optimal if, and only if, $q_M = q^*$ and $r_M = r^*$.

For any given values of γ and δ, there will be an infinite number of pairs of reaction functions that are mutually optimal. In fact, a pair of reaction functions specified by (6) will be mutually optimal if, and only if, the four numbers T_1, U_1, T_2, and U_2 satisfy the two constraints $q_M = q^*$ and $r_M = r^*$.

For example, consider the traditional case in which $\gamma = \delta = 0$ and each firm attempts simply to maximize its own profits. In this case it follows from equations (7) to (10) that the reaction functions given in (6) will be mutually optimal if, and only if,

$$\frac{1 - T_2}{2(1 + U_2)} = \frac{T_1 + T_2U_1}{1 - U_1U_2} \tag{11}$$

and

$$\frac{1 - T_1}{2(1 + U_1)} = \frac{T_2 + T_1U_2}{1 - U_1U_2} \tag{12}$$

After simplification, equations (11) and (12) can be rewritten as follows:

$$T_1 = T_2 = \frac{1 - U_1U_2}{(2 + U_1)(2 + U_2) - 1} \tag{13}$$

It can be seen from equation (13) that for any choice of the slopes U_1 and U_2 such that $|U_i| < 1$ $(i = 1, 2)$, there is a pair of mutually optimal reaction functions having those slopes. Furthermore, it is seen from equation (13) that the intercepts T_1 and T_2 must be equal in every pair of mutually optimal reaction functions.

The profits of the two firms will, of course, be different for different pairs of mutually optimal reaction functions. In particular, for a pair such that $U_1 = U_2 = U$, the point of intersection will be $q^* = r^* = 1/3 + U$ and the profit for each firm at this point will be

$$\pi_1 = \pi_2 = \frac{1 + U}{(3 + U)^2} \tag{14}$$

It follows from equation (14) that as U increases from -1 to $+1$, the profit for each firm increases from 0 to $\frac{1}{8}$, which is the profit that they can obtain by dividing the monopoly profits between them equally.

When $U = 0$, the mutually optimal reaction functions specify that both firms will repeatedly choose their outputs at the Cournot equilibrium point $q = r = \frac{1}{3}$. It should be noted that the usual Cournot reaction functions $q = \frac{1}{2}(1 - r)$ and $r = \frac{1}{2}(1 - q)$ are not mutually optimal even though their point of intersection is also $q = r = \frac{1}{3}$.

IV. Optimal Strategies in Multiperiod Decision Problems with Alternating Choice

We shall now consider again a process with n periods and shall assume that the two firms choose their outputs in alternating periods as described earlier in this paper. In our previous paper we developed pure duopoly strategies for the two firms by using the method of backward induction based on the assumption that each firm desired to maximize its total profit over the n periods. Here we shall generalize this development to a problem in which the coefficients of cooperation γ and δ of the two firms are fixed, firm 1 desires to maximize the utility V_1 given by equation (1), and firm 2 desires to maximize the utility V_2 given by equation (2).

For each different pair of values of γ and δ, the method of backward induction specifies a different sequence of outputs for the two firms which, in turn, yield a different sequence of profits for the firms over the n periods. Thus, the choice of γ and δ by the firms fixes their profit stream over the n periods. Suppose, for example, that $\gamma=\delta$, so the firms are using the same coefficient of cooperation, and suppose that c_1 and c_2 are numbers such that $0 \leq c_1 < c_2 < 1$. Then, in general, the profits of both firms will be higher when $\gamma=\delta=c_2$ than they will be when $\gamma=\delta=c_1$. In other words, it will be mutually profitable for the firms to use a common coefficient of cooperation that is as large as possible. The development given in our previous paper (see Cyert and DeGroot (1970a)) corresponds to the problem in which $\gamma=\delta=0$, and the development to be sketched here for arbitrary values of γ and δ is completely analogous to the development given there.

We shall assume for convenience that the total number of periods n is even and that firm 2 must choose its output r_n in the final period n. After the output q_{n-1} of firm 1 in period $n-1$ is known, firm 2 will choose r_n to maximize its utility $\pi_2(q_{n-1}, r_n) + \delta\pi_1(q_{n-1}, r_n)$. Thus, when firm 1 chooses its output q_{n-1} in period $n-1$, it knows the output r_{n-2} of firm 2 in period $n-2$ as well as the reaction function that firm 2 will use in period n. Hence, subject to these conditions, it can choose q_{n-1} to maximize its utility over the final two periods

$$[\pi_1(q_{n-1}, r_{n-2}) + \gamma\pi_2(q_{n-1}, r_{n-2})] + [\pi_1(q_{n-1}, r_n) + \gamma\pi_2(q_{n-1}, r_n)]$$

By moving backward through the process in this way, it is seen that at any given period, the firm which must choose its output in that period will know the reaction functions that will be used by the rival firm and by itself in all later periods. Hence, for any given output of the rival in the preceding period, it can choose its own output to maximize the sum of its utilities over all the remaining periods. The sequences of reaction functions for the two firms constructed in this way are called the *pure duopoly strategies relative to the given coefficients of cooperation* γ *and* δ.

If this process of backward induction is continued indefinitely and the reaction functions for the firms are derived for earlier and earlier periods, then these reaction functions will typically converge to certain limiting reaction functions. These limiting reaction functions are presented in the Appendix for the problem in which the demand function is linear and the profit functions of the two firms are given by (5).[5] In this problem, the reaction function used in each period and the limiting reaction functions of both firms are linear functions.

It is shown in the Appendix that when

[5] The relations (A1) to (A13) given in the Appendix which govern the backward induction process and the limiting reaction functions, include a discount factor as discussed later in this paper. These relations can be applied to the problem being considered here, in which the profits of the firms over the n periods are not discounted, by letting $\rho=1$.

the profit functions of the two firms are given by (5) and the coefficients of cooperation γ and δ are fixed, the limiting reaction functions are mutually optimal. More generally, as described in our previous paper, a wide class of quadratic profit functions can be reduced to the form (5) by an appropriate choice of the units of measurement (see Cyert and DeGroot (1970a)). In particular, it follows, therefore, that in any problem in which the demand function is linear and the costs of the two firms are assumed to be zero, the limiting reaction functions will be mutually optimal.

Because of the nature of the process by which the pure duopoly strategies are derived, we believe that for a wide class of profit functions other than quadratic ones, it will remain true that the limiting reaction functions are mutually optimal. However, at the present time this property has been established only for the quadratic functions described here.

V. Changing Coefficients of Cooperation

Up to this point we have established the following conclusions:

1. For each fixed pair of coefficients of cooperation γ and δ, there exists an equilibrium point obtained from mutually optimal limiting reaction functions.

2. There exists a unique pair of paths leading to each such equilibrium point established by a process of backward induction in which each firm wants to be in the optimal position vis-à-vis its competitor at the final point.

3. When $\gamma=\delta=0$, the equilibrium point is the noncooperative solution obtained in our previous paper. When $\gamma=\delta$ and their common value increases toward the value 1, the equilibrium point yields higher profits for both firms.

These conclusions mean that each firm can be viewed as facing a decision set consisting of an infinite number of pairs of multiperiod decision paths. Each of these pairs of paths leads to an equilibrium point established from mutually optimal reaction functions. Each pair is identified by the values of the coefficients of cooperation held by each firm. On each path the alternating decisions assumption holds. In each decision period the firm making the decision in that period makes the optimum decision, given the rival's decision in the previous period, for maximizing its utility over the infinite horizon. This entire process is, of course, based on the assumption that neither demand nor cost conditions are changing.

It is not however, necessary to assume that the coefficients of cooperation are fixed throughout the entire process. Each firm can change its coefficient of cooperation at any time. Hence, no firm need stay on a fixed path.

In order to illustrate the model's potential, let us start with a situation in which both firms are on the paths consistent with the values $\gamma=\delta=0$. Assume that through the process of learning, one of the firms develops a probability distribution on the rival's likelihood of cooperating with a larger value for the coefficient of cooperation. Specifically, let firm 1 have a uniform prior distribution for firm 2's coefficient of cooperation δ on the interval $0\leq\delta\leq d$, where 0 is the current value of δ and d is the highest level of cooperation to which firm 1 believes firm 2 will implicitly consent. Let us further assume that if d is less than the value of γ that firm 1 uses, then firm 2 will keep $\delta=0$, and that if $\gamma\leq d$ then firm 2 will match its coefficient of cooperation and choose $\delta=\gamma$.

If we assume a two-period analysis, then it is possible to determine an optimal value for γ, the value that firm 1 should set. Let $W_1(\gamma\,|\,0, d)$ stand for the expected utility of firm 1 over the two periods for a given value of γ $(0\leq\gamma\leq d)$. The expression

for W_1 must take into account the fact that decisions are made in alternating periods. We assume a process in which each firm is proceeding along the optimum paths for $\gamma=\delta=0$. In the period appropriate for firm 1 to make its output decision, it does so on the basis of the previous output r_0 of firm 2, but with a new choice of γ. By choosing an output q^* that is consistent with r_0 and a new value of $\gamma>0$, firm 1 indicates to firm 2 that it is prepared to operate at a higher level of cooperation than previously. Firm 2 then has the opportunity to respond positively, that is, to choose an r_1^* based on q^* and $\delta=\gamma>0$, or to continue to hold $\delta=0$ and choose an r_2^* based on $\delta=0$ and q^*. On this basis, firm 1 must choose γ to maximize the following expected utility:

$$W_1(\gamma \mid 0, d) = [\pi_1(q^*, r_0) + \gamma\pi_2(q^*, r_0)] + \frac{d-\gamma}{d}[\pi_1(q^*, r_1^*) + \gamma\pi_2(q^*, r_1^*)] + \frac{\gamma}{d}[\pi_1(q^*, r_2^*) + \gamma\pi_2(q^*, r_2^*)]$$

Since q^*, r_1^*, and r_2^* are also functions of γ, the maximization process becomes messy although straightforward. The question is whether there is a value of $\gamma>0$ such that $W_1(\gamma|0, d)>W_1(0|0, d)$. Some economic insight can be gained by regrouping the terms in $W_1(\gamma|0, d)$ and examining the resulting expression. We have

$$W_1(\gamma \mid 0, d) = [\pi_1(q^*, r_0) + \pi_1(q^*, r_1^*)] + \gamma[\pi_2(q^*, r_0) + \pi_2(q^*, r_1^*)] + \frac{\gamma}{d}\left\{[\pi_1(q^*, r_2^*) - \pi_1(q^*, r_1^*)] + \frac{\gamma^2}{d}[\pi_2(q^*, r_2^*) - \pi_2(v^*, r_1^*)]\right\}$$

It is reasonable to assume that the first two expressions are positive. The third one should be negative since we would expect firm 1 to make more profit when firm 2 cooperated by making $\delta=\gamma$. The fourth term should be positive since we would expect firm 2 to make more profit by being uncooperative (while firm 1 is being cooperative) than by being cooperative. Thus, the impact of firm 2's noncooperative action on firm 1 becomes decisive in determining whether the expected utility is increasing and in determining the size of the optimum γ if W_1 is positive. The larger the absolute value of the third term, the smaller the optimum value of γ will be. This result, of course, is not surprising since it is the response of firm 2 to firm 1's action that is the uncertain element in the situation.

Though this analysis is for the two-period case, it illustrates the process by which the firms can move from one track leading to a mutually optimal equilibrium to another. It is possible in this way for the firm to move from the uncooperative track, $\gamma=\delta=0$, to the higher profits corresponding to $\gamma=\delta=1$. Once learning takes place and the optimal value of γ becomes $\gamma^*>0$, firm 1 can rationally attempt to move to the new track, namely the one for which both $\gamma=\delta=\gamma^*$. Firm 2 then has two alternatives. It can refuse to follow and make larger profits than it did previously. However, it can expect firm 1 to come back eventually to the track represented by $\gamma=\delta=0$. Under such a situation firm 2 is back to its original profit position. If firm 2, on the other hand, moves to the new track by making $\delta=\gamma^*$, its profits will be greater than they were for $\delta=\gamma=0$. With the usual assumptions about demand and cost curves it is reasonable to assume that profits and hence utility become greater as $\gamma=\delta\rightarrow 1$.

It is possible to extend the analysis for the optimum new coefficient of cooperation to more periods than the two assumed. It is possible to view the expected utility over n periods and to solve for the optimum decision horizon as well as the

optimum coefficient of cooperation. It is also possible to postulate a different decision rule for the firm initiating the move to the higher level of cooperation. We assumed that firm 1 determined its output q^* based on the γ and the current output of firm 2, r_0. Many other decision rules might have been used by firm 1. The main point is that firm 1 wants to behave in such a way that firm 2 clearly understands that firm 1 is signalling a change in the level of cooperation.

The process just described continues to occur over time. If firm 1's efforts succeed and firm 2 increases its δ to make it equal to γ, then both firms are on a track leading toward a new mutually optimal equilibrium point. Both firms are making more profits than they were when each was on the uncooperative track. Both firms continue to learn and form priors about the new values toward which the other firm will raise its coefficient of cooperation. At some point when the decision rule being used shows that the expected gain in utility is worth the risk of increasing the coefficient of cooperation, one of the firms will make the move and eventually the firms will move to another pair of tracks where the profit is higher. In this model either firm may initiate the movement.

Even if the first move should fail to stimulate the rival to match the new coefficient of cooperation, eventually the process will succeed. The temporary gains from not matching will be lost as soon as the firm initiating the upward movement reduces its coefficient of cooperation back to the old. Punishment is as effective a stimulus for learning for real firms in the real world as it is for subjects in an experiment in a laboratory.

We argue, therefore, that this model demonstrates the kind of behavior that many economists have speculated does occur in duopoly and oligopoly. We have shown how firms progress from a noncooperative solution to situations of increasing profit and ultimately to the tracks characterized by $\gamma=\delta=1$.

The dynamicization of the duopoly model has been accomplished by the introduction of the concept of firm learning, by the formalization of the learning through Bayesian analysis, and by utilizing the concept of mutually optimal equilibria all within the format of multiperiod analysis. We believe this pattern of concepts can also be used to extend and improve other duopoly and oligopoly models (see Cyert and DeGroot (1971)).

VI. Discounting

Up to this point no mention has been made of the discounting process. We have made our analysis with the discount rate equal to zero. Such an assumption is, of course, unrealistic.

We shall continue to consider an n period problem in which the coefficients of cooperation of the two firms are γ and δ. We shall assume, however, that instead of desiring to maximize the sum (1), firm 1 desires to maximize the following discounted sum

$$(15)\quad V_1 = \sum_{i=1}^{n} \rho^{i-1}[\pi_1(q_i, r_i) + \gamma\pi_2(q_i, r_i)],$$

where ρ is the discount factor and is equal to $1/(1+r)$, where r is the discount rate. Thus $\rho=1$ is equivalent to no discounting ($r=0$) and $\rho=0$ implies $r=\infty$. Similarly, it is assumed that firm 2 desires to maximize the discounted sum

$$(16)\quad V_2 = \sum_{i=1}^{n} \rho^{i-1}[\pi_2(q_i, r_i) + \delta\pi_1(q_i, r_i)]$$

When the firms choose their outputs in alternating periods, the optimal sequence of reaction functions can again be found by backward induction. As before, if the process of backward induction is continued indefinitely and the reaction functions are derived for earlier and earlier

periods, these reaction functions will typically converge to certain limiting functions.

These limits are presented in Table 1 for various values of γ and δ (with $\gamma=\delta$) and various values of ρ, for the simple model for which the profit functions π_1 and π_2 of the two firms are given by (5). The relations governing the backward induction process in this model are presented in the Appendix.

It follows from the relations given in the Appendix, and it can be seen in Table 1, that for a discount factor of 0 ($r=\infty$), the solution for a coefficient of cooperation of 0 is the Cournot solution. However, as the discount factor increases (r decreases) so that the future is weighted more heavily, a zero coefficient of cooperation does not lead to the Cournot solution. In fact, for higher discount factors the Cournot output and profit (but not the Cournot reaction functions) can be found at higher coefficients of cooperation. This fact reemphasizes the point made in our earlier paper (see Cyert and DeGroot (1970a)) that the Cournot solution requires a certain amount of trust. Thus for the true noncooperative solution (coefficient of cooperation $=0$) the profit continues to fall as the discount factor increases. For any given discount factor $\rho<1$ it can be seen that the firms move toward the monopoly solution as the coefficient of cooperation increases and attain it when the coefficient is equal to one.

It should be pointed out, however, that when a discount factor is present, the

limiting reaction functions obtained from the backward induction process will not be mutually optimal.

VII. Summary and Conclusions

This paper presents an extensive generalization of the work that Cournot began in 1839. We have generalized the number of periods involved in the analysis. We have introduced the concept of the coefficient of cooperation and have shown that by varying the discount factor ρ and the values of the coefficients of cooperation γ and δ an infinite number of equilibrium positions are possible. Only one combination, $\rho=0$ and $\gamma=\delta=0$, gives the classical Cournot solution; although the Cournot equilibrium values are shown to exist for $\gamma=\delta>0$ for $\rho<1$. In fact, for any value of ρ there is a value of γ and δ that will give the Cournot values.

Cournot had to restrict his firms to a single assumption about their rival's behavior. By the introduction of the concept of learning and by making the management of each of the firms Bayesians, we are not required to restrict our firms to a single position with respect to their rival during the course of the analysis. We also free the analysis of the traditional criticism against Cournot, i.e., the management of each firm is stupid and does not learn even though the rival firm repeatedly behaves contrary to assumption (see George Stigler). In our model the firm can learn more about the nature of his rival and this learning affects the value of the coefficient of cooperation set by the firm. In the model developed in this paper, either firm may function as the leader in trying to move the two firms to a higher profit track represented by an increased

value of the coefficient of cooperation. The decision is made (or not made) to move to a higher track by one of the firms on the basis of a probability distribution developed through learning applied to expected profits. We demonstrate that the process of learning with changing priors on the rival's behavior enables the firms to move to the monopoly solution, given that $\rho<1$. We also show that for $\rho=1$ and for $0\leq\gamma\leq1$ and $0\leq\delta\leq1$, each track for the firms results in a mutually optimal equilibrium position. This result does not hold when $\rho<1$, in other words, when the future is discounted.

Appendix

We shall derive here the optimal strategies for each firm when the profit functions in each period are given by (5), the coefficients of cooperation are γ and δ, and firms desire to maximize the discounted sums V_1 and V_2 given by (15) and (16). When $\rho=1$, equations (15) and (16) reduce to equations (1) and (2), so the discussion which follows includes as a special case the problem in which there is no discounting ($\rho=1$).

As far as possible, we shall follow the notation of our previous paper (see Cyert and DeGroot (1970a)). It is assumed that the total number of periods n is even, that firm 1 must choose its output q_j in each odd period j, and that firm 2 must choose its output r_k in each even period k.

By backward induction the optimal choice of firm 1 in period j can be shown to be a linear function of the output r_{j-1} of firm 2 in period $j-1$. We shall denote this optimal choice by

$$q_j^* = t_j + u_j r_{j-1} \tag{A1}$$

When firm 1 chooses the output q_j^* and all subsequent choices by the two firms on periods $j+1$ to n are also made optimally, it can be shown by backward induction that the sum of the utilities for both firm 1 and firm 2 on periods j to n will be quadratic functions of r_{j-1}. If $F_j(r_{j-1})$ denotes the sum of these utilities for firm 1 and $G_j(r_{j-1})$ denotes the sum for firm 2, then these sums are of the form:

$$F_j(r_{j-1}) = A_{j-1} + B_{j-1}r_{j-1} + C_{j-1}r_{j-1}^2 \tag{A2}$$

$$G_j(r_{j-1}) = D_{j-1} + H_{j-1}r_{j-1} + L_{j-1}r_{j-1}^2 \tag{A3}$$

Similarly, firm 2 must choose the output r_k in each even period k. The optimal value of r_k will be a linear function of q_{k-1} which we shall denote

$$r_k^* = t_k + u_k q_{k-1} \tag{A4}$$

With this choice of r_k and optimal choices of outputs by the two firms on all subsequent periods from $k+1$ to n, the sum of the utilities for firm 2 on periods k to n, as a function of q_{k-1}, will be denoted

$$G_k(q_{k-1}) = A_{k-1} + B_{k-1}q_{k-1} + C_{k-1}q_{k-1}^2 \tag{A5}$$

The sum of the utilities for firm 1 will be denoted

$$F_k(q_{k-1}) = D_{k-1} + H_{k-1}q_{k-1} + L_{k-1}q_{k-1}^2 \tag{A6}$$

All the coefficients in equations (A1) to (A6) can be found by backward induction beginning with the final period n. For any even integer k and any given value of q_{k-1}, we have

$$\begin{aligned} G_k(q_{k-1}) = \sup_r \big[&\pi_2(q_{k-1}, r) \\ &+ \delta\pi_1(q_{k-1}, r) + \rho G_{k+1}(r)\big] \end{aligned} \tag{A7}$$

The value of r that yields the supremum on the right side of equation (A7) is r_k^*. The value of $F_k(q_{k-1})$ can then be determined by the relation

$$\begin{aligned} F_k(q_{k-1}) = \ &\pi_1(q_{k-1}, r_k^*) \\ &+ \gamma\pi_2(q_{k-1}, r_k^*) + \rho F_{k+1}(r_k^*) \end{aligned} \tag{A8}$$

For any odd integer j, similar relations exist for determining the values of $F_j(r_{j-1})$, q_j^*, and $G_j(r_{j-1})$.

Since the values of $G_{n+1}(r_n)$ and $F_{n+1}(r_n)$ must be 0, the backward induction begins with the boundary values

$$A_n = B_n = C_n = D_n = H_n = L_n = 0 \tag{A9}$$

For any even integer k, the following rela-

tions can be derived from equations (A4) to (A8):

$$\text{(A10)}\qquad t_k = \frac{1+\rho H_k}{2(1-\rho L_k)}$$

$$u_k = -\frac{1+\delta}{2(1-\rho L_k)}$$

$$A_{k-1} = \rho D_k - \frac{(1+\delta)t_k^2}{2u_k}$$

$$B_{k-1} = \delta - (1+\delta)t_k$$

$$C_{k-1} = -\left(\delta + \frac{(1+\delta)u_k}{2}\right)$$

$$D_{k-1} = \rho A_k + (\gamma + \rho B_k)t_k + (\rho C_k - \gamma)t_k^2$$

$$H_{k-1} = 1 - (1+\gamma)t_k + (\rho B_k + \gamma)u_k + 2(\rho C_k - \gamma)t_k u_k$$

$$L_{k-1} = (\rho C_k - \gamma)u_k^2 - (1+\gamma)u_k - 1$$

Similarly, for any odd integer j, a completely analogous set of eight equations can be derived by replacing k by j everywhere in (A10) and interchanging γ and δ wherever they occur in (A10).

If the backward induction process is continued indefinitely and the values of t_k and u_k are calculated for successively smaller even integers k, it is found that these values converge to certain limiting values, which we shall denote by T_2 and U_2. Similarly, the values of t_j and u_j for odd integers j will converge to certain limiting values T_1 and U_1. In other words, the reaction functions (A1) and (A4) converge to certain limiting reaction functions of the form

$$\text{(A11)}\qquad q_j^* = T_1 + U_1 r_{j-1}$$

$$\text{(A12)}\qquad r_k^* = T_2 + U_2 q_{k-1}$$

By replacing t_k, u_k, B_{k-1}, B_k, C_{k-1}, C_k, H_{k-1}, and L_{k-1} by their limiting values in (A10), and replacing t_j, u_j, B_{j-1}, B_j, C_{j-1}, C_j, H_{j-1}, and L_{j-1} by their limiting values in the analogous equations for odd integers j, it is found that the limiting values T_1, U_1, T_2, and U_2 must satisfy the four equations shown as (A13). If $\gamma=\delta$, then $T_1=T_2$ and $U_1=U_2$, and it can be found from (A13) that the common value of T and common value of U must satisfy the relations shown as (A14).

Now suppose that $\rho=1$, so that there is no discounting. When $\gamma=\delta$ it follows from equations (7) to (10) that the limiting reaction functions given by (A11) and (A12) will be mutually optimal if, and only if,

$$\text{(A15)}\qquad T = \frac{(1-U)(1+\delta U)}{3+\delta+(1+3\delta)U}$$

$$\text{(A13)}\qquad \delta = \frac{(1+\rho)(1+\rho T_1 - 2T_2) - \rho(2+\rho+\rho U_1U_2)(T_1+T_2U_1)}{\rho[2+\rho+2(1+\rho)U_1+\rho U_1U_2](T_1+T_2U_1) - \rho(1+\rho)(T_1+U_1)}$$

$$\delta = -\frac{(1+\rho U_1U_2)^2 + 2(1+\rho)U_2}{(1+\rho U_1U_2)^2 + 2\rho(1+\rho)U_1^2U_2}$$

$$\gamma = \frac{(1+\rho)(1+\rho T_2 - 2T_1) - \rho(2+\rho+\rho U_1U_2)(T_2+T_1U_2)}{\rho[2+\rho+2(1+\rho)U_2+\rho U_1U_2](T_2+T_1U_2) - \rho(1+\rho)(T_2+U_2)}$$

$$\gamma = -\frac{(1+\rho U_1U_2)^2 + 2(1+\rho)U_1}{(1+\rho U_1U_2)^2 + 2\rho(1+\rho)U_1U_2^2}$$

$$\text{(A14)}\qquad \rho^2(1+\delta)U^4 + 2\rho(1+\rho)\delta U^3 + 2\rho(1+\delta)U^2 + 2(1+\rho)U + 1 + \delta = 0,$$

$$T = -\frac{(1+\rho)(1+\rho\delta U)U}{1+\delta-\rho(1+\delta)U-(\rho^2+3\rho^2\delta+2\rho\delta)U^2-\rho^2(1+\delta)U^3}$$

It can now be verified that if T and U satisfy the relations (A14), then they also satisfy (A15). Hence, the limiting reaction functions (A11) and (A12) are mutually optimal.

An analytic proof that the limiting reaction functions (A11) and (A12) are mutually optimal when $\rho=1$ and $\gamma \neq \delta$ has not been obtained. However, these limiting reaction functions have been computed numerically by carrying out the backward induction process for a wide range of values of γ and δ and it has been verified that in every case the limiting reaction functions are indeed mutually optimal.

Tables 1 and 2 and this Appendix contain a number of interesting and often surprising results which have been obtained from the simple linear model and are worth summarizing.

1. If $\rho=1$, then for any given values of γ and δ, the limiting reaction functions will be mutually optimal.

2. When $\gamma=\delta$ and $\rho=1$, the profits of both firms at the equilibrium point are larger, the larger is the common value of γ and δ. As this common value of γ and δ approaches the value 1, the equilibrium point converges to the Cournot equilibrium point and the profits converge to the Cournot equilibrium profits. However, the reaction functions do not converge to the Cournot reaction functions. They converge to a mutually optimal pair of reaction functions intersecting at the Cournot equilibrium point. It should have been emphasized that the limiting relations (A13) and (A14) have been derived under the assumption that γ and δ are strictly less than 1. These relations are not valid for $\gamma=\delta=1$ because the backward induction process does not lead to a unique equilibrium for these values.

3. If $\gamma<\delta$, then the profits of firm 1 at the equilibrium point will be greater than the profits of firm 2. As firm 1 increases γ up to the level of δ, the profits of firm 1 do not necessarily monotonically decrease. They may continue to increase until γ gets close to δ, and then start to decrease. For example, when $\gamma=.2$ and $\delta=.9$, the profits of firm 1 are greater, and the profits of firm 2 are smaller than they are when $\gamma=0$ and $\delta=.9$.

4. For any fixed value of $\rho (0 \leq \rho < 1)$ if $\gamma=\delta$, then as their common value approaches the value 1, the equilibrium point converges to the collusive solution. Hence, no matter how close to 1 the value of ρ is, as long as $\rho<1$, the profits of both firms converge to the pure cooperative profits as γ and δ converge to 1.

Alternative Programs for Income Redistribution: The NIT and the NWT

By EDGAR K. BROWNING*

Economists have devoted considerable attention to the analysis of the advantages and disadvantages of the negative income tax (*NIT*) as a mechanism for income redistribution. Surprisingly little attention has been given to any significantly different alternative to the *NIT*—most analyses simply compare one variant of the *NIT* to another. But recently several writers have suggested that a form of wage subsidy offers significant advantages over the *NIT*.[1] This paper is an attempt to provide a more complete comparision of these two forms of transfer programs with an emphasis on the aggregate labor market consequences. Needless to say, no attempt is made to consider all repercussions of these policies. Instead, emphasis is focused on labor supply effects and related conditions for economic efficiency.

Section I is an analysis of the effects of implementing a *NIT* when no other transfer programs are present. Section II is a similar analysis for a form of wage subsidy which will be referred to as the negative wage tax, or *NWT*. Section III uses the analysis of the preceding sections to provide a comparison of the *NIT* and *NWT* on two counts: their incidence and welfare cost.

* Assistant professor of economics, University of Virginia. I am grateful to Roland N. McKean, John H. Moore, Edgar O. Olsen, and Roger P. Sherman for comments on an earlier draft. This paper draws on materials from chapters 2, 4, and 7 of my doctoral dissertation. I am especially indebted to Wallace E. Oates, my dissertation supervisor, for his encouragement and assistance.

I. The Negative Income Tax

The *NIT* is the name given to a cash transfer program where the transfer varies inversely with the household's income: the lower the income, the greater the transfer. The mechanics of such a program are probably familiar, but will be summarized briefly in order to show the similarity to the *NWT*. The transfer received by a household, then, is

$$T = r(B - Y) \tag{1}$$

where T is the transfer payment, r is the marginal tax rate (sometimes called the negative tax rate), B is the level of income at which the transfer is zero, which is called the break-even level, and Y is the income of the household. This equation gives the transfer for any household with income below the break-even level.

A *NIT* program is described by its three policy variables: r, B, and the income guarantee, which is simply the transfer that a household with a zero income receives. But only two of the policy variables are independent, since if B and r are set, then equation (1) specifies the transfer where Y = zero (the income guarantee).[2]

In analyzing such a program it will be assumed initially that market wage rates do not change. Figure 1 illustrates the

[2] For a discussion of the relationships among the policy variables, see Christopher Green.

conventional indifference curve analysis of the effects of the *NIT* on work effort and income. *AP* is the budget constraint relating income and leisure in the absence of the *NIT*, with a slope of (−) the wage rate. Equilibrium occurs at *E*, with income of *EE′* and work effort of *PE′*. When the *NIT* is implemented, the constraint becomes *AKM*, where *K* is the break-even income corresponding to *B* in equation (1), and *MP* is the income guarantee. The disposable income of the household will be higher than its earned income for any level of earned income between zero and *B*. The *KM* portion of the constraint is flatter than the original constraint which indicates that the net marginal wage rate of the household is lower under the *NIT*. This is a result of the marginal tax rate of the *NIT*, since the slope of *KM* is equal to $(1-r)$ times the market wage rate. Thus, the higher is r the lower is the net marginal wage rate.

This change in the budget constraint has two implications of importance to our analysis.[3] The first is that the work effort of the household receiving the *NIT* transfer will be reduced. The effect on work effort can be divided into an income effect and a substitution effect. The income effect results from the transfer raising income at each level between zero and the break-even level, and part of this increment will be taken as increased leisure if leisure is a normal good. The substitution effect results from the marginal tax rate which lowers the net marginal wage rate, thus causing a substitution of leisure for income. Assuming leisure to be a normal good, both the income and substitution effects of the program tend to produce a reduction in work effort. The new equilibrium is illustrated at *F* in Figure 1, with

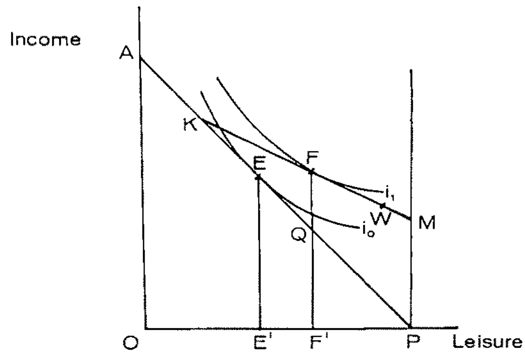

FIGURE 1

work effort equal to *PF′*, earned income of *QF′*, and a transfer of *FQ*. Note that the income of the household has not been increased by the full amount of the transfer because of the reduction in work effort.

That a *NIT* tends to produce a reduction in work effort is well known, but a second implication of the analysis has received much less attention: it is possible that work effort will be reduced sufficiently to reduce the income (money income, not real income, of course) of the household. Thus, an equilibrium may occur at *W* in Figure 1 because the income and substitution effects on income are in opposing directions and the outcome depends on the size of the opposing influences. If the substitution effect is larger then, a *NIT* will actually result in a reduction in the income of the transfer recipient.

This is a somewhat distressing implication of the theory and it thus may be worthwhile to assess its likelihood. The effect on income depends on the size of the substitution effect relative to the income effect: the larger the substitution effect, the more likely is a reduction in income. The substitution effect is a consequence of the tax rate in the program, and since this rate is (normally) the same for all households with income between zero and the break-even level, we can say, roughly, that the stimulus to substitute away from in-

[3] Depending on how the income tax is coordinated with the *NIT*, these implications may also hold for some households with income above the break-even level.

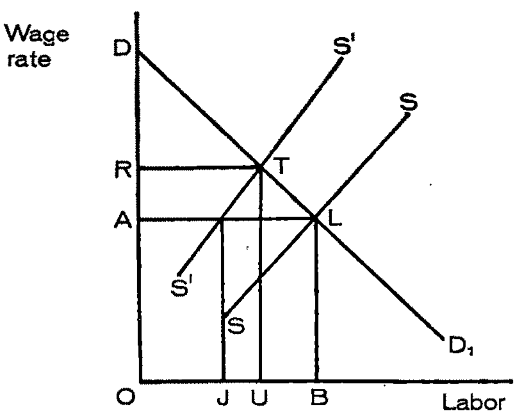

FIGURE 2

come is the same. But the income effect depends on the size of the transfer, and this is smaller the closer is income to the break-even level. Therefore the substitution effect is *relatively* more important the higher is income, and the income effect is *relatively* more important the lower is income, so the likelihood of a reduction in income is greater the higher is income.[4]

So far we have assumed that market wage rates will remain unchanged. This assumption has allowed us to get an idea of the initial reactions to a *NIT*, but this is not the complete picture because wage rates can be expected to change in response to introduction of the *NIT*. If the market for labor services of the transfer recipients is in equilibrium before the *NIT* is introduced, and the *NIT* results in a reduction in the quantity of labor supplied at the existing market wage rate, then the market will no longer be in equilibrium. The quantity demanded will exceed the quantity supplied and the wage rate will be bid up. Thus, the analysis of Figure 1 is incomplete for the final equilibrium cannot lie on the budget constraint *AKM* since this constraint is based on the lower market wage rate that prevailed before the *NIT* was implemented.

To evaluate the effects of this change in wage rates, we have to analyze the aggregate labor market repercussions. In Figure 2, DD_1 and *SS* are the demand and supply curves in the absence of the *NIT* program. They are drawn for the households whose labor services will be in reduced supply as a result of the *NIT*, which we can think of, roughly, as the transfer recipients. *OA* is the initial market wage rate and *OALB* the earned income of the recipients. Since Figure 2 represents an aggregate labor market, *ODLB* is total national income which is divided between the transfer recipients, *OALB*, and the rest of society, *ADL*.[5]

The *NIT* results in a leftward shift in the supply curve to $S'S'$, where the reduction in the quantity of labor supplied at the initial wage rate, *JB*, is simply the sum of the reductions such as $E'F'$ illustrated in Figure 1. Assuming that the other factors of production are in inelastic supply, the demand curve will not shift. Then the equilibrium is at *T*, with a wage rate of *OR* and quantity of labor *OU*. The total income of the transfer recipients will be *ORTU* plus the transfers received (which are not shown in the diagram).

This has several important implications for an analysis of the *NIT*:

1) As we saw earlier, it was possible for the income of the transfer recipients to fall. Once we take account of the increase in the wage rate, however, the likelihood of this occurring is lessened. To see why, think of the total change in income as the

[4] That this is plausible can be seen by examining two extreme cases. If income is initially at the break-even level (*K* in Figure 1), income will definitely be reduced by the *NIT* since there is only a (Slutsky) substitution effect. On the other hand, if income is initially below the income guarantee, then the *NIT* will definitely increase income.

[5] Identifying the area under the demand curve as total income assumes that total income would be zero if the quantity of transfer recipient labor is zero. If this is not the case, then a constant term must be added to *ODLB* to give total income. In addition, identifying *OALB* as the income of the transfer recipients assumes that they have no nonlabor income.

sum of the change which would occur if the wage rate did not change and the subsequent change when the wage rate increases. The first change (illustrated in Figure 1) may result in a reduction in income, as we saw. But the wage rate increase will always increase income from this level, since an increase in the wage rate is the same as a reduction in the "effort" price of income and, hence, more income will be consumed.[6] This will be true regardless of the slope of $S'S'$ as long as the law of demand holds. The net effect on income may still be negative, but it is less likely due to the increase in the wage rate.

2) The change in the earned income of the transfer recipients resulting from the *NIT* will not be an indication of the disincentive effect. Earned income may rise despite a significant reduction in work effort if the wage rate rises sufficiently. If the demand curve is inelastic, then earned income for the entire group will rise following a reduction in labor supply, and conversely.

3) The taxation necessary to finance the transfer cost of the *NIT* will not measure the actual cost borne by the rest of society. This is because the gross (pretax) income of the rest of society will be reduced, reflecting the lower marginal productivity of other factors of production when the quantity of transfer recipient labor they are combined with in production falls.[7] In Figure 2, this reduction in the gross income of the rest of society is from *ADL* to *DRT*, or *ARTL*. The area *ARTL* represents an implicit transfer of income which occurs within the private sector as a result of changes in factor prices and is as much a cost to the taxpayers as the explicit transfer cost of the program.[8]

II. The Negative Wage Tax

The negative wage tax is a transfer program which assists households by subsidizing the prices at which they sell their labor services. The form discussed here is a type of wage subsidy which is similar to the *NIT*. But instead of the subsidy varying inversely with income, as with the *NIT*, it varies inversely with the wage rate of the household. The relationship among the variables is given by

$$S = s(W_s - w) \tag{2}$$

where S is the subsidy per hour of work, s is the rate of subsidy (a fraction), W_s is the break-even wage rate at which the subsidy is zero, and w is the market wage rate.[9] This equation does not represent the total transfer to the household, since the total transfer will be equal to S times the number of hours worked.

Analysis of this program is quite simple. Assume initially that market wage rates do not change when the *NWT* is introduced. Then the budget constraints of all *NWT* transfer recipients will be changed in exactly the same way as if their market wage rates increased, with larger increases the lower is the initial market wage rate. As is well known, the substitution and income effects of such a change are in opposing directions and the impact on work effort is indeterminate. If the household's labor supply curve is upward sloping work effort increases, and conversely if it is backward bending. Without knowledge of the slope of the supply curve no definite prediction can be made.

[6] See Lionel Robbins.

[7] It is possible that the prices of specific factors which are good substitutes for transfer recipient labor will rise. But, on average, the price of all other factors must fall.

[8] In an earlier article in this *Review* I extended this analysis to show that an experimental simulation of a *NIT* will not produce unbiased estimates of the effects of the program.

[9] The similarity between the *NIT* and the *NWT* is apparent from a comparison of equations (2) and (1).

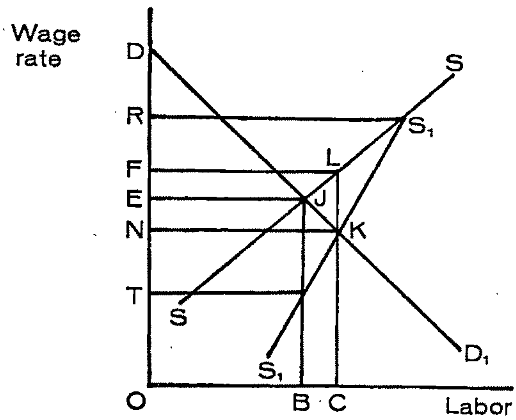

FIGURE 3

Income (the transfer plus earned income) will definitely be increased by the *NWT*. An increase in the wage rate is equivalent to a reduction in the effort price of income, as already mentioned, so more income will be chosen. (In effect, the law of demand places a limit on how backward bending a supply curve can be.)

One other implication should be noted, because of its contrast to the *NIT*. With the *NIT* all households with income below the break-even level will face a net marginal wage rate that is one half their market wage rate (if $r=.5$). This means the substitution effect would be relatively more important compared with the income effect for incomes near the breakeven level. This is not true with the *NWT*: the income and substitution effects will both be smaller near the break-even wage rate because the divergence between the net and market wage rates becomes smaller as we approach the break-even wage rate. For example, if $s=.5$ and $W_s=\$2$, at a market wage rate of \$1 there is a \$.50 difference between the market and net wage rate, whereas at a market wage rate of \$1.90 the difference is only \$.05. Thus, the substitution effect of the *NWT* will tend to be smaller at higher wage rates. As we will see later, this has important implications for assessing the welfare cost of the *NWT*.

Now we will drop the assumption that market wage rates do not change and examine the impact of the *NWT* on the labor market. In Figure 3, DD_1 and SS represent the market demand and supply curves in the absence of the *NWT*: these are the same curves as in Figure 2 if the same households are being subsidized. The equilibrium market wage rate is OE, and the quantity of labor is OB. The gross income of the rest of the community is initially EDJ.

The *NWT* drives a wedge between the market wage rate, which will determine the quantity of labor services employers will wish to employ, and the net wage rate, which will determine the quantity of labor services households will wish to provide. The supply curve with quantity expressed as a function of the market wage rate becomes S_1S_1S. For wages above W_s (OR in Figure 3), the supply curve is unchanged, since there is no subsidy paid for wages above this level. Below this point the vertical difference between the two supply curves is equal to the subsidy per unit. For example, households would be willing to supply OB units of labor at a market wage of OT with the *NWT* in effect, since this implies a net wage rate of OE. With an upward sloping supply curve, therefore, the *NWT* will increase the supply of labor.

This increase in supply results in a new equilibrium at K, with a lower market wage rate (ON) and a higher net wage rate (OF) than previously. If the supply curve is vertical the *NWT* will result in no change in the market rate but a higher net rate, and if it is backward bending the result is a higher market and a higher net wage rate. Only in the perverse case where the demand curve is vertical would the net wage rate received by the recipients fail to increase.[10]

[10] This analysis breaks down if $s=1$. In this case the supply of labor to each *firm* becomes independent of the

The implications of this analysis parallel those discussed with reference to the *NIT*: 1) The total income of the transfer recipients will always be increased by the *NWT* so long as the demand curve is downward sloping. This follows from the fact that the net wage rate will increase regardless of the slope of the supply curve. 2) The change in earned income of the transfer recipients is not an indication of the incentive or disincentive effects of the program since earned income depends on the change in the wage rate as well as the change in hours worked. 3) The transfer cost again does not measure the burden borne by the rest of society. However, for the *NWT*, it is not possible to predict a priori whether the actual burden will be greater or less than the transfer cost, for this depends on the shape of the supply curve. If the supply curve is upward sloping, the actual burden borne by the rest of society ($FLKN-EJKN$) is less than the transfer cost ($FLKN$) by the increase in the gross income of the rest of society ($EJKN$). If the supply curve is backward bending the actual burden is greater than the transfer cost because there will be a reduction in labor supply just as with the *NIT*.

III. Comparison of *NIT* and *NWT*

The analysis in the previous sections gives some useful insights into the workings of two alternative welfare programs, but it is lacking in several respects. In each case the analysis was designed to show the effects of the programs on the obviously unrealistic assumption that no other welfare programs exist. Moreover, the analysis also neglects a number of considerations which are relevant in evaluating a transfer program. For instance, the effects on family size and stability, criminal activity, voting behavior, investment in human capital, and occupational choice may be of considerable importance in evaluating the costs and benefits of a transfer program. However, in a comparison of the *NIT* with the *NWT* at the same level of redistribution, these effects may be kept the same, and therefore not crucial to the analysis. Many of these side effects are undoubtedly related more closely to the income effects of the redistribution than to its particular form, so if we compare programs of equal magnitude we can assume that these side effects will not differ substantially and concentrate on those factors where differences will exist, for example, on labor market effects.

One objection to a comparison of the *NIT* and *NWT* is that the two programs cannot be made comparable since a *NWT* will provide no assistance to those who do not work; whereas under the *NIT* these households will receive the income guarantee. This objection is quite valid and the fact that the *NWT* affects only those who work represents a real drawback. But this drawback is not decisive, for it is possible to use a companion program with the *NWT* to deal with these households. Such a companion program could take several forms, but for our purposes we will simply assume that it provides the same amount of assistance to nonworking households as would the *NIT*. This means that these households will be in similar circumstances under the *NWT* and *NIT*, and we can simply ignore them and concentrate on working households in the analysis.

A. Differential Incidence

Now we will compare the distributional effects of a *NIT* and *NWT* by applying to transfer programs Richard Musgrave's concept of "differential incidence," where-

market wage rate, since the net wage rate would then be W_e regardless of the market wage rate. This implies that the market wage rate would fall to zero and the taxpayers would be bearing all the labor costs. To avoid this it is necessary to maintain adequate differentials in net wage rates for different market wage rates, and this means that s should be significantly below one.

by one tax is conceptually substituted for another and the consequences traced out.[11] The *NIT* and *NWT* must be of equivalent magnitudes for this comparison. But care must be taken in specifying what determines equivalent magnitudes. The most obvious criterion, equal transfer cost, is not appropriate. As we have seen, the transfer cost does not generally measure the burden on the rest of society of either the *NIT* or the *NWT*, so that programs of equal transfer cost may impose unequal burdens on the taxpayers.

Unfortunately, in dealing with a tax plus a transfer program, the definition of equivalence is somewhat arbitrary: one may define equivalence from the standpoint of either the taxpayers or the transfer recipients. Consequently, we will examine both alternatives. Initially, equivalence will be defined as programs which imply the same money income for the transfer recipients. (Ideally, this should be done for equal real income, but this is impossible without a precise knowledge of utility functions and an ability to apply different policy variables to each recipient. Hence, we must content ourselves with equating money income.) And, secondly, equivalence will be defined as programs which imply the same real burden for the rest of society (the taxpayers).

Neither definition is fully acceptable when the analysis is applied to the group case, as ours will be, since the analysis may gloss over distributional effects within each group. For instance, an equal money income for the entire group of transfer recipients under each program may be accompanied with a very different distribution of that income among the recipients. But the seriousness of this is mitigated by the possibility of using graduated marginal tax rates or rates of subsidy, and thereby allowing some control over the distribution of a given money income under either program. Accordingly, we will ignore this complication.

Initially, we will compare programs which result in equal money income for the transfer recipients. The supply and demand curves for the labor services of the recipients in the absence of any welfare program (or in the presence of any welfare program which will remain in effect with both the *NIT* and *NWT*) are shown in Figure 4. Consider the *NWT* plan which shifts the supply curve to S_1S_1. Assume that a *NIT* program which results in the same money income for the transfer recipients shifts the supply curve to S_2S_2. There is no way, of course, to show in the diagram that this *NIT* produces exactly the same money income as the *NWT*. But for our purposes this is not important, since we need only know (as we will see) that the supply curve with the *NIT* lies to the left of the supply curve of the comparable *NWT*. And this will always be the case.[12]

Therefore, when a *NIT* and *NWT* result in the same money income, the quantity of labor supplied will be greater under the *NWT*. The importance of this is that it implies that total national income will be greater under the *NWT* even with a

[11] See Musgrave, ch. 10.

[12] For an upward sloping supply curve this is obvious, since the two programs shift the supply curve in opposite directions. With a backward bending supply curve both programs shift the supply curve to the left, but the shift is greater for the *NIT*. To see why, imagine that the leftward shift is equal for the *NIT* and *NWT*, producing the same market wage rate under both programs. This cannot be an equilibrium, for income and leisure are identical under both programs, yet the net wage rates differ. The same income and leisure cannot represent an equilibrium under both programs, for while there is no difference in the income effects at this point, there remains a substitution effect favoring more work (less leisure) under the program with the higher net wage rate. The *NWT* implies the higher net wage rate, since the net wage under it will exceed the market wage rate, while the net (marginal) wage rate under the *NIT* is always below the market wage rate. This means that an equilibrium with equal income under the two programs must imply greater leisure under the *NIT*.

backward bending supply curve, so the following analysis will remain valid whatever the shape of the supply curve.

Now let us determine under which of the programs there is the greater burden on the rest of society. This can be determined by taking the following measurements from the diagram.

Total national income:

1. Under $NWT = DKCO$
2. Under $NIT = DHAO$

Total income of the transfer recipients:

3. Under $NWT = TKCO +$ transfer cost
4. Under $NIT = FHAO +$ transfer cost

Total money income of the rest of society (which will also be an indication of total real income since we have assumed inelastic supplies of its factors of production) will be:

5. Under $NWT = DKCO - (TKCO +$ transfer cost)
6. Under $NIT = DHAO - (FHAO +$ transfer cost).

This shows that the income of the rest of society is simply the difference between total national income and the income of the transfer recipients. Recall that the transfer programs have been designed so that the income of the transfer recipients (the bracketed terms in the above relationships) are equal, so we can subtract the sixth relationship from the fifth to get:

7. $DKCO - DHAO = HKCA$

$HKCA$ is the amount by which the real income of the rest of society is greater under the NWT than under the NIT. It is simply the difference in national income under the two policies.

Thus, in raising the income of the transfer recipients to any desired level, the real burden on the rest of society is lower under a NWT than under a NIT. Despite the somewhat lengthy derivation above, this is intuitively obvious once it is recognized that national income is greater under the NWT, for the income of the transfer recipients is identical in both cases, and the remainder of total income is the income of everyone else in society.

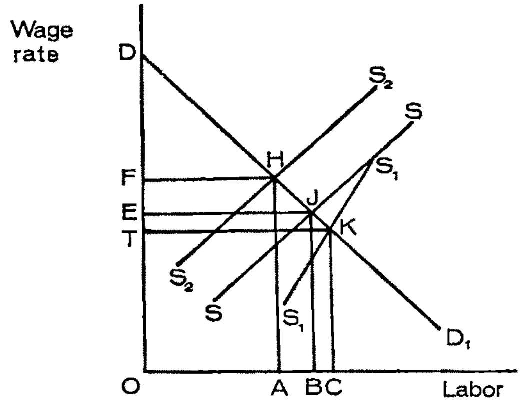

FIGURE 4

It must be noted, however, that equal money income under the two programs does not imply equal real income for the transfer recipients because the quantity of leisure will differ for the two programs. In fact, since leisure will always be greater under the NIT, the transfer recipients (ignoring possible distributional effects within the group) will be better off under the NIT.

Alternatively, we can compare the NIT and NWT when they are designed to produce the same burden on the rest of society, i.e., where the net income of the taxpayers is the same. The same procedure can be used to show that, since national income will still be greater under the NWT, the income of the transfer recipients will be greater under the NWT. Thus, at equal real cost to the rest of society, the NWT raises the income of the transfer recipients by a greater amount. In this case it is not possible to generalize concerning the welfare of the transfer recipients, for while they have greater income under the NWT they have less leisure.[13]

[13] These same results can be derived for an individual using indifference curve analysis, but this approach suffers from the assumption that the market wage rate will be the same under both programs.

B. Welfare Cost

In the absence of market imperfections, any form of non-lump sum transfer payment results in a welfare cost, or excess burden. For the *NIT* the welfare cost reflects the fact that the marginal tax rate drives a wedge between the market wage rate and the net marginal wage rate, leading the recipient to consume too much leisure; if he received the same payment in the form of a lump sum transfer, he would consume more income and less leisure and would be better off. There is also a welfare cost associated with the *NWT*, but here the recipient is led to consume too little leisure and too much income relative to the distortionless lump sum transfer. This difference is due to the fact that the *NWT* involves negative marginal tax rates which result in the net wage rate being greater than the market wage rate, whereas the opposite is true for the *NIT*.

Since both forms of transfer programs produce a welfare cost, it might appear that nothing a priori can be said about their relative sizes. But this is not true. There are good theoretical reasons for believing that the welfare cost of a *NWT* will be smaller than that of a comparable *NIT*. To show this, we will draw on the work of Arnold Harberger concerning the measurement of welfare cost. Harberger shows that the welfare cost of an income tax can be expressed as:

$$\text{(3)} \qquad \text{Welfare cost} = (1/2)em^2wL$$

where e is the elasticity of labor supply (expressing the substitution effect alone),[14] m is the marginal tax rate on income, w is the market wage rate, and L is the quantity of labor supplied.[15] The total welfare cost of the income tax is simply this expression summed over all households.

While this formula was derived by Harberger to measure the welfare cost of an income tax, it can also be used to measure the welfare cost of a transfer program if the transfer payment varies with the household's income. When the transfer varies with income there is an implicit marginal tax rate which drives a wedge between market and net wage rates, and this ensures that the formula is applicable. It makes no difference if the implicit marginal tax rate on income is negative, as it is with the *NWT*.

Now we can give three reasons why a *NWT* is likely to produce a lower welfare cost than a comparable *NIT*.[16]

1. Assume that the marginal tax rate of the *NIT* is .5 and the elasticity of labor supply is the same for all recipients. Then the welfare cost as a percentage of gross earnings is constant for all recipients: it is $(1/2)em^2wL/wL$, or $(1/2)em^2$. Now consider a comparable *NWT* with a rate of subsidy of .5. The welfare cost as a percentage of gross earnings is also $(1/2)em^2$, but for the *NWT* this percentage *falls* as the wage rate of the household is closer to the break-even wage rate. This is because the implicit marginal tax rate on income is not given by the rate of subsidy, but instead is a negative function of the market wage rate.

For example, consider a *NIT* with $B=\$6000$ and $r=.5$, and a *NWT* with $W_s=\$3$ and $s=.5$. At a market wage rate of \$1.50, the negative tax rate (m) under the *NWT* is $-.5$, but at higher wage rates

[14] It is important to recognize that there will be a welfare cost associated with an income tax even if the supply curve as normally drawn, including both income and substitution effects, is perfectly inelastic. The welfare cost reflects the substitution effect of the tax; hence, e in (3) will always be positive.

[15] The derivation of this formula depends on the assumption that distortions other than those arising from the income tax are negligible.

[16] The welfare cost associated with the taxation necessary to finance the programs will be ignored on the assumption that it will be the same for both programs.

it becomes progressively smaller. For instance, at a market wage rate of \$2, m equals $-.25$ since the subsidy here is \$.50 per hour. Thus the *NWT* will involve a lower welfare cost for all households with wage rates above \$1.50 than will the *NIT*, and a higher welfare cost for those with lower wage rates. (This simply reflects the fact that the distortion between market and net wage rates is smaller the higher is the wage rate under the *NWT*, whereas the distortion is the same (in percentage terms) at all wage rates for the *NIT*.) Since most recipients will be in the former category and since the base (ΣwL) is almost certain to be larger here, the total welfare cost is likely to be smaller under the *NWT*.

2. A second factor contributing to a lower welfare cost for the *NWT* is the existence of other taxes and transfers which impose positive marginal tax rates on the recipients of *NIT* or *NWT* transfers. For example, state and local income taxes, general sales taxes, the social security tax, and many state welfare programs all involve positive marginal tax rates.

The existence of these other programs with the same type of welfare cost as the income tax (reflecting their positive marginal tax rates) has two relevant implications. The first is that the additional welfare cost of the *NIT* (one cannot now speak of *the* welfare cost of the *NIT*) will be higher than in the absence of these other programs. The second is that the additional welfare cost of the *NWT* will be lower than in the absence of these programs, and may be negative (a welfare gain).

The welfare cost of a *NIT* as a percentage of gross earnings is $(1/2)em^2$, or is proportional to the square of the marginal tax rate. If $r=.5$, the welfare cost is proportional to .25 if there are no other programs imposing a marginal tax rate on income. But since there are such programs, assume for purposes of illustration that the effective marginal rate (roughly, the sum of the marginal rate of each program)[17] of other programs on income is .2. Then there is a welfare cost prior to implementation of the *NIT* which is proportional to .04. With the *NIT* in effect, the effective marginal rate will be $.7(=.5+.2)$ and the *total* welfare cost will be proportional to $(.7)^2$, or .49. The *additional* welfare cost of the *NIT* will be proportional to $.45(=.49-.04)$. Note that this is substantially higher than the .25 figure we arrive at when we ignore the existence of these other programs.

Thus, the existence of other programs with positive marginal tax rates implies that the additional welfare cost attributable to the *NIT* is larger than it would be in the absence of these programs.

Exactly the opposite is true for the *NWT*: the additional welfare cost is lower when programs with positive marginal tax rates on income exist. The reason is that the effective rate will be the sum of the negative rate of the *NWT* and the positive rate of the other programs: the negative rate of the *NWT* tends to offset the positive rate of the other programs. Or, to put this another way, the distortion of the *NWT* is in the opposite direction from the distortion of the other programs, and this means that the *NWT* will tend to offset some of the distortion introduced by the other programs. For example, at a wage rate where the negative tax rate of the *NWT* is $-.2$, then the total welfare cost will be proportional to $(-.2+.2)^2$, or will be zero since the negative rate of the *NWT* exactly offsets the positive rate of

[17] The effective rate may not be exactly equal to the sum of the marginal rates of each program because the bases of the different taxes may differ. For instance, the effective rate due to the federal income tax and a state income tax is less than the sum because state tax liability is deductible in computing federal tax liability.

the other programs yielding an effective rate of zero. The additional welfare cost of the *NWT* is then proportional to $-.04$, or represents a welfare gain equal to the initial welfare cost of the other programs.

To get an idea of the importance of this, consider again the *NIT* and *NWT* programs discussed earlier (with $B=\$6000$, $r=.5$; $W_s=\$3$, $s=.5$). If the effective tax rate of the other programs is .2, then at any wage rate exceeding \$1.06 the additional welfare cost of the *NWT* will be less than that of the *NIT*. At \$1.06, both programs imply an effective net rate of .7 (in absolute value); for the *NIT* this is $(.5+.2)$ and for the *NWT* $(-.9+.2)$. At higher wage rates the effective rate under the *NWT* is lower. In fact, at wage rates exceeding \$1.67 (where the net effective rate under the *NWT* is $-.2$) there will be a welfare gain as a result of introducing the *NWT*, for the effective rate (absolute value) in the \$1.67–3.00 range will actually be lowered below the preexisting rate of the other programs.

Thus, the *NWT* tends to offset some of the distortions already existing in the system. By contrast, the *NIT* will aggravate these distortions still further.

3. So far the analysis has relied on an implicit assumption which many economists would question, i.e., that a lump sum transfer (with a zero marginal tax rate) is an efficient device (involves a zero welfare cost). This would be the case if there are no externalities associated with the responses of the recipients to the transfer payments. But if there are externalities of certain kinds, then lump sum transfers (which provide the benchmark for a zero welfare cost in (3)) will not be efficient.

Recently, Richard Zeckhauser has argued that externalities may be important in determining the optimal structure of income transfer programs. In effect, he suggests that the money income of the poor is an external economy to the taxpayers, while they do not care (or care less intensely) about the welfare or leisure of the poor.[18] Zeckhauser shows that if this type of interdependence exists then Pareto optimality (i.e., absence of a welfare cost) in a transfer program requires that it have a negative marginal tax rate on income. While his analysis is somewhat involved, the key idea is quite simple: at equal cost to themselves taxpayers prefer (at least up to some point) a transfer program which results in more money income and less leisure for the recipients. At equal cost, a program with a negative tax rate (for example, the *NWT*) will produce more money income and less leisure than a program with a positive rate (for example, the *NIT*) or a zero rate (for example, lump sum transfers). Hence, a program with negative rates will be preferred by the taxpayers. In addition, Zeckhauser's more rigorous formulation demonstrates that the transfer recipient as well as the taxpayer may benefit in moving from a program with a positive rate to a program with a negative rate.

If this assumption is valid, then for a program to involve a zero welfare cost it must use a negative tax rate on income.[19] This implication strengthens our conclusions regarding the relative welfare costs of a *NIT* and a *NWT*. For in this case Harberger's formula must be reinter-

[18] The assumption of this type of interdependence is probably less implausible than most such assumptions. As evidence, it should be noted that virtually all of the literature defines poverty in terms of money income alone, rather than as money income plus the value of leisure time.

[19] Presumably, there is an optimal structure of negative rates rather than a single optimal rate for all the poor. It seems plausible that the optimal rate for a household with an income of \$2000 will be larger (in absolute value) than for a household with an income of \$4000. This would simply reflect a greater concern on the part of the taxpayers to raise the incomes of the poorest households. If this is true, then a *NWT* policy is an appropriate remedy, for the negative rates will tend to be higher for poorer households.

preted: the marginal tax rate (m) in the formula must measure the divergence of the actual marginal rate from the optimal negative rate and not from zero. This means that any *NIT* will result in an even greater additional welfare cost, since the difference between its positive rate and the optimal negative rate will be larger than the difference between its positive rate and zero. On the other hand, a *NWT* will appear even better in comparison with the *NIT*.

These three reasons taken together make a convincing case that a *NWT* will produce a lower welfare cost than a *NIT*. While there is certainly no presumption that any real world *NWT* would be optimal, it will at least tend to alter the tax rate structure in the proper direction, whereas the *NIT* will tend to exacerbate the distortions already present.

One other matter deserves comment. For a *NWT* to function properly it is important that the minimum wage law be repealed. It does little good to subsidize low wage rates heavily if the law prohibits employment at these wage rates. After all, a *NWT* allows the attainment of the objectives of the minimum wage law, which is something that cannot be said for the law itself. Many economists feel that repeal is long overdue in any event, but it is worth emphasizing that it will be all the more important if a *NWT* is implemented.

Simulation of the Impact of Social and Economic Institutions on the Size Distribution of Income and Wealth

By FREDERIC L. PRYOR*

In the vast literature on the distribution of income, relatively little systematic attention has been paid to the mutual influence of the distributions of income and wealth on each other, and to the impact of intergenerational grants on the entire process. The purpose of this essay is to utilize a simulation model in which the distributions of income and wealth are analyzed together. The model permits me to explore the influences of such socioeconomic variables as the pattern of intergenerational grants, the rules of inheritance, the patterns of mate selection, differential fertility of various income classes, and the patterns of governmental redistributions of income and wealth. So many simplifying assumptions must be made that the model, as it is presented below, cannot be directly used for determining the current size distribution of income and wealth; nevertheless, the results of the model suggest certain neglected factors, particularly the shape of the intergenerational savings function, that must be taken into account if we are to gain a clearer picture of the causal forces operating in the real world. The most important biases (mostly leading to greater income equality) arising from the simplifying assumptions of the model are also discussed below.

To take all the major long-run factors influencing the size distributions of income and wealth into account is an extremely complicated matter, and we face two alternative research strategies; either we model these factors mathematically, which requires some drastic simplifications in order to keep the equation system solvable,[1] or we take more factors into account by simulating their impact. While the latter procedure does not lead to a completely general solution it does permit us to investigate certain features of economic systems using parameters of particular interest.

To place this model in perspective, it is useful to note that variance of personal income can be derived from three sources; variances in the distribution of labor income, of property income, and of the interaction between these two variables.[2] In this model, variations of labor income are handled by assigning everyone a lifetime income equal to the average lifetime in-

* Professor of economics, Swarthmore College. I wish to thank Howard Pack, J. Roland Pennock, Frank C. Pierson, Zora Pryor, and George Stolnitz for their helpful suggestions on an earlier draft. The research for this essay was financed by the International Development Research Center of Indiana University and was carried out at the Economic Growth Center of Yale University. A considerable amount of difficult work was done by those who programmed this extremely complicated simulation model, and I would especially like to thank the chief programmer, Carol Hopkins. I would also like to express my appreciation to David Forman and Michael Hooven for assistance at particular points.

[1] Such an approach is followed by Joseph Stiglitz and, in a less formal fashion, by James Meade.

[2] The higher the correlation between individual labor and property incomes, the more unequal the distribution of income. (See formula in fn. 11.) The correlation can, of course, be negative, a situation that apparently arose in mandarin China where receivers of property income made a special point of avoiding manual work, even if it meant a lifetime of poverty. (See Hsiao-Tung Fei.)

come times a random variable with a mean of unity and a specified standard deviation. Variations in property income stem only from differential holdings of wealth; returns per unit of wealth are assumed equal; and, finally, no correlation is assumed between individual labor and property incomes. Thus the critical factor for a change in the distribution of income is a change in the distribution of wealth which, in turn, is greatly influenced by the different socioeconomic variables specified below.

I. The Basic Model[3]

The simulation model starts with 100 unmarried people with an arbitrary initial distribution of productive wealth. These people are "put to work" and both lifetime labor and property incomes are generated by means of a production function (a Cobb-Douglas function is used at first but a *CES* function is later tried) with assumptions of full employment and of mean factor payment equal to its marginal product. The total amount of property income is divided among all wealth holders in amounts proportionate to the quantity of wealth held by each; the total amount of labor income is distributed to the entire population by giving each a wage equal to the average wage times a normally distributed variable (which is supposed to represent a differential distribution of abilities such as intelligence or diligence).

The people in the model are then lined up according to income, and marriages are arranged according to one of three different rules: 1) A person can only marry another person next to him on the income scale (this is called the no-choice rule); 2) The chances for a person marrying anyone else are equal (the equal-choice rule); 3) A person can marry anyone but the chances are greater if the two are closer to each other on the income distribution (the limited-choice rule).[4]

The government can then step in and redistribute income (either progressively or regressively). This is followed by the accumulation or disposal of family wealth (positive or negative savings) so that a specified ratio of family wealth to family income is achieved; this intergenerational savings function is discussed in detail below. A simplifying assumption used in the model is that all wealth and net changes in wealth (net savings or dis-savings) are in the form of productive capital which yield property income.

At this point the various families have children according to their income in the following manner: First, the families are divided into three groups according to whether they are among those with the highest family incomes, lowest incomes, or in-between. (The percentage of families falling in each group can be varied.) Then the number of children are specified for each group, for example, the rich can be designated to have more or fewer children than the poor (or vice versa). Polygynous situations can be approximated by specifying many children for the rich and no children for the poor, since in such societies it is well known that only the wealthier can afford to support many wives and the low income men often do not marry.

The parents are then removed from the scene and family wealth is divided among

[3] The model rests on the pioneering work of Guy Orcutt. Other simulation models of income distribution have been made (for example, Hans-Juergen Krupp), but these are considerably different than mine and, moreover, have focused primarily on short-run problems.

[4] The probabilities of one person marrying another is, of course, changed when a couple is married and removed from the pool of eligibles. Therefore, the statements in the text must be considered as just approximately true. For the limited-choice model, the probability of marriage is inversely proportional to the difference in income rank between the two individuals. The calculations are simplified by not designating the sex of the individuals so that marriages between any two individuals may be possible.

the children according to one of three different rules: 1) One child can receive everything (the primogeniture rule);[5] 2) The property can be divided equally among all children (the equal-division rule); 3) The first child can receive half of the wealth and the remainder is divided equally among the rest (the compromise rule). At this point the government can also redistribute wealth (a type of inheritance tax). We now have a group of people with a given distribution of wealth of productive capital whom we put to work; the process is repeated many times to see if a stable distribution of income and wealth is achieved.

With only a few exceptions (discussed below) the processes converge toward an "equilibrium distribution" which, when attained, is maintained for all succeeding generations. In certain cases, however, the process is extremely slow and in order to avoid inordinate computer expenses, the following procedure was adopted. In every case the simulation was carried out twice, once starting from a highly unequal initial distribution of wealth (where the wealthiest 10 percent of individuals share the total societal wealth in equal portions) and once starting from a relatively equal wealth distribution (where the wealthiest 75 percent of individuals share in equal amounts the total wealth). Each simulation is then run for 30 generations (which represents 1000 years if a generation is calculated as $33\frac{1}{3}$ years, or 750 years if a generation is 25 years) and the end results of the simulations starting from different points are averaged; in almost all cases the two estimates were very similar to each other.

[5] I have used an extreme form of primogeniture in which the first child, regardless of sex, obtains the entire family's wealth. This variant of primogeniture leads to the most extreme wealth-holding inequalities and, in addition, is computationally simpler in that sexes do not need to be assigned to particular individuals for the model to work. A more usual case of primogeniture is, of course, when only the eldest son obtains the entire estate.

In the tables I use Gini coefficients as a measure of this inequality of the equilibrium size distribution of lifetime income. Gini coefficients are measured by calculating Lorenz curves and measuring the ratio between the "area of inequality" and the total income triangle (the coefficient ranges from 0.00, which represents total equality to 1.00, which represents total inequality). I have computed four other statistical measures of inequality but space does not permit their inclusion. In certain cases where it is useful to discuss relative speeds of convergence, the period is measured from the starting point to the point when an equilibrium Gini coefficient is achieved (plus or minus a small amount).[6]

Before the numerical results are presented, certain features of the model may perhaps be better understood if we examine in a qualitative fashion the effect of particular variables.

A. The Simplest Patterns

If we take a situation where every family, regardless of income, has two children; where there is no variation in labor income (the random factor is not yet introduced); and where families do not add to, or decrease, their inherited wealth (i.e., family wealth is passed on unchanged regardless of income, a situation occurring when land is the basic source of wealth and is not alienable), the observed patterns of convergence of the distribution of wealth are quite simple and are outlined in Table 1 below.

With primogeniture wealth accumulates eventually into a single hand.[7] The speed of convergence is inversely proportional to the degree to which people choose marriage partners in other income brackets. With

[6] The exact method employed is described in the Appendix.

[7] If the eldest son variant of primogeniture is used, then, of course, this extreme result will not obtain.

TABLE 1—BASIC EQUILIBRIUM PATTERNS OF THE DISTRIBUTION OF WEALTH

	Marriage rules		
Inheritance rules	No-choice rule	Limited-choice rule	Equal-choice rule
Primogeniture	Wealth concentrates to a single owner; fast convergence.	Same as no-choice rule, but convergence is slower.	Same as no-choice rule, but convergence is slower than other primogeniture situations.
Equal division	Wealth distribution remains the same as starting position.	Wealth becomes evenly distributed but convergence is slow.	Wealth becomes evenly distributed; convergence is faster than with limited-choice rule.

equal division of inherited property and with everyone marrying a person next to him on the income distribution, it should be readily apparent that no change will occur in the size distribution of income and wealth, as long as all families continue to have two children. In the other two cases with equal division of inherited property, wealth eventually becomes completely equally distributed.

The compromise rule of inheritance, where the first child received half of the property and the remainder is divided equally among the other children, is the same as the equal-division rule (under the assumption of two-child families).

The speed of conversion to equilibrium depends, of course, on the distribution of wealth at the starting point and at equilibrium. Starting from a highly unequal distribution of income, convergence is achieved in the primogeniture case in three to five generations; starting from the more equal distribution of wealth, convergence takes six to fifteen generations. For the equal-division cases where convergence occurs, the process generally takes somewhat longer. Although convergence speeds in the above examples appear to have little economic meaning, they become important when governmental policy measures are introduced (i.e., redistribution of income and/or wealth) and certain goals of income distribution are set.

B. The Impact of a Random Variable Representing Abilities

If we now introduce a random variable representing differential abilities so that labor incomes are the product of the average wage times a random variable (with a mean of unity), the basic patterns are modified in the following ways:

1) The greater the variation in the random element, the more unequal the equilibrium income distribution in those five cases in Table 1 where convergence is observed. This is because greater extremes in labor income are generated.

2) In situations where people are allowed choice in marriage partners, the convergence process is speeded up where there is an equal division inheritance rule and slowed down where there is primogeniture. This stems from the fact that there is a greater mixing of people of different wealth at the time of marriage (since the marriage rules are based on total income, not wealth alone). Where people marry those next to them on the income scale, a complication arises which is discussed below.

One important methodological point also arises. Introduction of a random element raises difficulties in determining the exact equilibrium distribution of income. In interpreting the various tables presented below, small differences in the coefficients should be overlooked and, al-

though data are presented to three places, variations of several percent or less should usually be neglected.

Throughout the remaining simulations the random factor is set with a standard deviation of 15 percent, which is roughly similar to the variation of I.Q. test scores.

C. The Impact of Differential Fertility Rates

In all cases primogeniture leads to a highly unequal income distribution since, whatever the fertility pattern, only one child receives all the property. Similarly, in all cases where the rich have only one child (which leads automatically to primogeniture) a highly unequal equilibrium income distribution is also generated.

In nonprimogeniture cases, fertility affects the end results considerably. In cases where fertility increases with income, the system should converge relatively quickly to fairly even distributions. (Such a situation allegedly occurred in past eras in oriental despotic societies where the rulers encouraged polygyny so that the rich would have a much higher fertility rate than other classes and, at the same time, forbade primogeniture; the end result was supposed to be an economy with a relatively even distribution of income and no independent bases of wealth with which to challenge royal authority.)[8]

Simulation results of different patterns of fertility among the income classes are presented in Appendix Table 1. For simplicity, in the rest of the paper, I assume that fertility is the same in all income classes unless otherwise specified.

II. Quantitative Results: No Saving; Stationary Population; No Technological Change

We are now ready to begin the quantitative investigation. In Table 2 below, the results for the most simple situation with different marriage and inheritance rules are presented. There is no accumulation of wealth for the society as a whole and each family passes on only that wealth which it inherits.

[8] Such systems are analyzed by K. Wittfogel.

TABLE 2—GINI COEFFICIENTS OF EQUILIBRIUM INCOME DISTRIBUTION ASSUMING DIFFERENT MARRIAGE AND INHERITANCE RULES

	Marriage Rules		
Inheritance Rules	No-Choice	Limited-Choice	Equal-Choice
Primogeniture	.307	.308	.297
Compromise	[a]	.064	.060
Equal Division	[a]	.064	.060

Assumptions: No net family capital formation; no capital or income redistribution; all families have two children; standard deviation of the random element is .15; labor share of national income is 75 percent.

[a] If the system starts from a highly unequal distribution of wealth, the equilibrium distribution of income is equal to its original value. If the system starts from a relatively equal wealth distribution where high ability people with no property might marry low ability people with property (since they would be next to each other on the income scale), then the equilibrium income distribution would be highly equal.

As expected, the inequality of income is higher with primogeniture than with the compromise or equal division inheritance rules (which give the same answers because each family has only two children). As we also expect, the equilibrium income distribution does not seem greatly affected by the marriage rules; in this simple model the major effect of the marriage rules appears on the speed at which equilibrium is achieved. Only in much more complicated models do the marriage rules appear to have much impact on the equilibrium size distribution of income. One puzzling phenomenon appears in the primogeniture case where the other measures of inequality give somewhat different results but this is due most likely to a change in the shape of the distribution of income, with slightly increasing inequality at the high income end and slightly de-

creasing inequality at the middle and lower income levels. This particular result does not appear due to random factors since equilibrium was achieved from all starting points of the simulation and the various results given particular marriage and inheritance rules were very similar.

In the simulation model a wealth redistribution process can be set up so that all inherited wealth is taxed a given percentage and then the total amount of taxed wealth is distributed equally among all individuals. If the tax rate is positive, then such a process is progressive because the least wealthy end up with a net gain in wealth while the most wealthy end up with a net loss. This manner of specifying a capital tax on inherited wealth allows the total amount of privately held wealth to remain constant.

The results of imposing a capital redistribution tax are presented in Table 3 and can be summarized quite easily: The greater the redistribution of wealth, the more equal the equilibrium distribution of income and wealth. This, of course, is not surprising. The equilibrium income distributions are most unequal for the primogeniture cases and most equal when family property is evenly distributed among heirs, a result similar to the previous findings. The marriage rules again have a relatively small impact. It must be noted that with very high redistributions of wealth, the differences in the equilibrium distributions with the various marriage and inheritance rules are relatively small; it appears that after a certain point, the redistribution swamps the effects of other institutions.

Since the redistribution of wealth can be a deliberate tool of governmental policy, the rate of convergence to the equilibrium income distribution is of considerable interest. Several generalizations can be made: First, imposition of a redistribution of wealth greatly increases the speed of convergence and in almost all cases convergence is achieved within five generations (with the major portion of the changes occurring in the first two generations). Second, convergence appears to be faster when the model is started with relatively more unequal wealth distribution

TABLE 3—GINI COEFFICIENTS OF EQUILIBRIUM INCOME DISTRIBUTION WITH DIFFERENT REDISTRIBUTIONS OF WEALTH

Redistribution and inheritance rules	Marriage Rules: No-Choice	Limited-Choice	Equal-Choice
No redistribution of wealth			
Primogeniture	.307	.308	.297
Equal division	[a]	.064	.060
30 percent redistribution of wealth			
Primogeniture	.156	.158	.148
Equal division	.061	.063	.063
60 percent redistribution of wealth			
Primogeniture	.088	.091	.089
Equal division	.062	.062	.064
90 percent redistribution of wealth			
Primogeniture	.061	.066	.064
Equal division	.062	.062	.062

Assumptions: see Table 2
[a] See fn. a, Table 2

than with a relatively more equal wealth distribution. In other words, achieving a more equal distribution of income by means of a redistribution of wealth can be carried out more quickly in those cases where the differences between actual and desired distributions are greatest.

Introducing a redistributive income tax changes, of course, the equilibrium income distribution. In this case wealth is not affected; and since marriages are arranged according to relative income, this part of the system is not affected either. Under the assumptions in this section about no-net intergenerational accumulations of family capital, the speed of convergence toward the equilibrium income distribution should not be affected. However, once we allow net intergenerational accumulation of capital based on family income, then an income redistribution could have a number of effects on total savings, growth, and convergence and provides a much more interesting problem for analysis. Discussion of the effects of a redistributive income tax is therefore deferred until the rigid assumption about the integenerational transfer function is loosened.

III. Quantitative Results: Introduction of an Intergenerational Savings Function

Let us now allow the capital stock to change, while still keeping the total population constant, so that we can isolate some of the effects of different patterns of intergenerational savings and transfers. One of the most important results of the simulation exercise is to show that the shape of this function has crucial importance on the equilibrium income distribution. Before turning to the results, however, several theoretical questions deserve brief examination.

First we must inquire about the nature of the integenerational transfer function. Up to now this has been a *terra incognita* in the economic literature: empirical data with which to derive such a function are unavailable and theorists who insist on deducing propositions about consumer behavior from the neoclassical axioms of rational choice have not been able to say anything about the matter. One reasonable assumption, which is reflected in numerous *obiter dicta* on the subject, is that the amount of wealth passed on by a husband and wife to their children is primarily a function of lifetime family income and it is on this basis that the model is changed below. The shape of the function is still problematical and experiments are carried out with several different formulae.

Second, once we introduce changes in the net capital stock, a problem arises because we must also take into consideration the possibility of multiple stable growth paths;[9] thus the initial conditions of the system and the way in which the intergenerational transfer function are specified become quite important. In order to avoid such complications, care was exercised in designing the intergenerational transfer function so that only a single stable growth path, independent of the initial conditions, would be achieved. A number of tests were also made with different initial conditions (different initial capital stocks) in order to insure the correctness of the specification.

A third problem arises in the choice of the production function, i.e., the function showing the relationship between the capital and labor in the system and total production. All production functions used below exhibit diminishing returns to variations in the capital-labor ratio. This means, among other things, that the ratio of capital to labor asymptotically approaches a limit which represents a "steady-state equilibrium" where depreciation just equals gross savings and net

[9] This problem is analyzed in an abstract but lucid manner by Stiglitz.

capital formation is zero. Such diminishing returns can, however, be offset by technological change so that in "steady-state growth" production, the capital stock and the ratio of capital to labor rise at the same rate of growth. In this particular case (Harrod-neutral growth), labor productivity (the ratio of output to the constant labor force) also rises at the same rate while capital productivity asymptotically approaches a constant.

One last precautionary note must be added. Although the analysis below focuses almost exclusively on income distribution, it must be emphasized that the various types of intergenerational transfer functions, production functions, and redistributions of wealth and income lead to quite different equilibrium levels of production. Although there are a number of propositions in the economic literature linking the inequality of income to the growth rate of production (for example, the more unequal the distribution of income, the greater the aggregate production), the results below show exceptions to such generalizations. For those interested in pursuing the relationship between income distribution, the savings function and growth, some data on steady-state production equilibria are given in Appendix Tables 2, 4, and 6.

A. *The Impact of Linear and Non-Linear Intergenerational Transfer Functions*

Two types of integernerational transfer functions are used in the analysis below. The first is a simple linear function where intergenerational transfers of a particular family are a proportion of lifetime income: $S=Yz$ where S=intergenerational transfers; Y=family lifetime income; and z is the "savings constant" to be specified. If family income is low and inherited wealth is great, the intergenerational transfer (proportionate to income) might be less than the original inherited wealth, i.e., the family has "dipped into capital." A second type of intergenerational transfer function has a kink in it and is thus non-linear; such transfers are a function of income over and above some socially determined "subsistence level," below which no intergenerational transfers are made (i.e., the family doesn't pass on inherited wealth). Since negative intergenerational transfers (i.e., debts) are not permitted (although dipping into capital is allowed), the kink of the savings function occurs at $\overline{Y}$. The simple form selected for this non-linear function is $S=(Y-\overline{Y})z$, $S\geq 0$.

A brief digression is necessary to clear up certain ambiguities of this subsistence level. First, this is not necessarily the biological subsistence level nor does there need to be any explicit societal recognition that such a subsistance level actually exists. Rather, it is merely the income level below which families feel they must spend all of their funds for consumption in order to try to achieve a certain standard of living and as a result, they do not have any wealth left over to pass on to succeeding generations. If per capita income in the society rises and the socially determined subsistence level remains stationary, this subsistence level may eventually become such a small proportion of individual family income that the savings function is, for all intents and purposes, linear, i.e., the performance of the system asympototically approaches that of a system with an intergenerational transfer function of $S=Yz$. On the other hand, the socially determined subsistence level can also rise as society views on an adequate standard of living rise. Since this might be a reasonable approximation of reality, it is useful to tie the subsistence income to the rise in per capita income. For simplicity, I have set the subsistence income always equal to average per capita income which means that when a non-linear intergenerational transfer function is used, only those

TABLE 4—GINI COEFFICIENTS OF EQUILIBRIUM INCOME DISTRIBUTION ASSUMING DIFFERENT INTERGENERATIONAL TRANSFER FUNCTIONS

Assumptions: All families have two children; standard deviation of random element is .15; labor share of national income is 75 percent; no income or capital redistributions; no technical change; no negative transfers.
Note: S=intergenerational transfers; Y=personal incomes; $\bar{Y}$=average income; z=a constant.

families with incomes above the average pass on wealth to the succeeding generation. Finally, it must be noted that the socially determined subsistence level can rise faster than average income and in this strange case with such a strong "demonstration effect," families might dip into capital (as long as they did not run into debt) until little capital would be left in the society as the subsistence level approaches the highest family incomes.

Experiments were also made with a third form of the intergenerational transfer functions: $S=W+Yz$, where W is the wealth inherited by the mother and father of the family from their parents. This function implies that the wealth inherited by the children is always greater than the wealth inherited by the parents, no matter how low the family income might be because of the low labor incomes received by the parents. Such a situation does not seem very realistic and these experiments were abandoned. The results of simulation experiments using both linear and non-linear intergenerational transfer functions for several different parameters of the savings coefficient (z) are presented in Table 4 above.[10]

The non-linear transfer function leads,

[10] If the capital-output ratio is greater than unity, the average z coefficient must be greater than unity or there must be a multiplicative constant in the production function if the capital stock in the economy is to be maintained. In the results reported in Table 4, z is placed larger than unity. If a multiplicative constant were used in the production function, z could be made less than unity (which, of course, makes more "real life" sense) but the results would be the same.

as one might expect, to a much greater inequality of income than the linear function; for in the former case, only the richer segments of the population pass on wealth to their children and this, in turn, concentrates wealth and property income. With a simple linear transfer function, the height of the savings coefficient (z) does not appear to affect the inequality of the equilibrium income distribution (the differences do not appear statistically significant) although, of course, a higher z leads to a higher steady-state production level. On the other hand, a higher savings coefficient does seem to affect the degree of income inequality when a non-linear function is used, although the direction of the effect depends upon the particular measure of inequality that is chosen and the inheritance rule that is followed.

With the introduction of intergenerational transfer functions based on income, we now have a situation where the marriage rules have a more important impact on the equilibrium income distribution than in the previous section where capital was passed on regardless of income. With primogeniture the effect of the marriage rules is small in almost all cases except with one nonreported inequality measure. On the other hand, with equal division of property, especially with a non-linear transfer function, the inequality of the equilibrium income distribution decreases as the marriage rules change toward equal choice.

Generalizing about the relationsips between equilibrium income distribution, inheritance rules, and transfer functions is more difficult. With a linear intergenerational transfer function, primogeniture leads to a more unequal distribution of personal income than other inheritance rules. With a non-linear transfer function, the results depend upon the measure of inequality chosen since the relationships between different parts of the income distribution are differentially affected. Thus no generalization is possible.

To summarize, with a linear transfer function where families at all income levels pass on wealth to the succeeding generation, the primary influence on the equilibrium distribution of income is the inheritance rules; and marriage rules or the height of the savings constant (z) have little effect. With a non-linear intergenerational transfer function, the equilibrium income distribution is affected by the marriage rules, the inheritance rules, and the height of the savings constant. Generalizations in these latter cases are difficult because the overall inequality and the shape of income distribution curve change simultaneously.

B. The Impact of Income and Capital Redistributions

A redistribution of capital in each generation not only affects the distribution of income but also, in the case of a non-linear intergenerational transfer function, the growth of the system. (This is because the share of income over the subsistence level is a smaller ratio of total income after a redistribution). The effect on the equilibrium distribution of income should increase with the severity of the redistribution and, one might suspect, would greatly affect the equilibrium distribution in the case of a non-linear, rather than a linear, transfer function. Relevant data are presented in Table 5 below which supports these conjectures.

An X percent redistribution of income in each generation should have a greater impact on the equilibrium distribution of income than an X percent redistribution of wealth because in the latter case only one source of income inequality is being changed. This differential impact of an income redistribution should also be greater in the case of a non-linear intergenerational savings function because the effect on the

share of income over the subsistence level vis-à-vis the total national income would be greater. And finally, the effect of an income distribution should increase with the extent of the redistribution and (using the same arguments employed in the case of the capital redistribution) should affect the equilibrium distribution more in the case of the non-linear than of the linear transfer function. These conjectures receive support in the data presented in Tables 5 and 6 although certain exceptions do arise, especially when other inequality measures are used. Although the underlying reasons for these exceptions are obscure, part of the difficulty may lie in the changing shape of the income distribution curve that accompanies the overall changes in equilibrium inequality.

Again, we observe the fact that convergence to the equilibrium income distribution is very much speeded up with the imposition of either a redistribution of income or wealth tax program. Again, convergence is achieved usually in a few generations although the parameters of the equilibrium are somewhat different than those discussed in Section II.

Since these income or capital taxes may serve as deliberate policy tools by the government to achieve particular income distribution goals, we must turn briefly to the convergence properties of the system. In the case of the linear intergenerational transfer functions, the situation is very similar to the case where there was no net capital formation in each family and convergence occurs very rapidly, usually in

several generations. In the case of the non-linear intergenerational transfer function, the system approaches the equilibrium distribution equally rapidly; but in the wealth redistributions, the Gini coefficient of income inequality often cycles around the equilibrium value several times, rather than asymptotically approaching it.

Since the greatest changes in income equality brought about by the income or wealth redistribution occur in the first generation and since differences between the actual degree of income inequality and the equilibrium value are quite small after a few generations, one lesson seems clear: other things being equal, redistribution taxes appear an efficient method of changing the degree of income inequality in a nation. (One condition in the *ceteris paribus* clause is that such taxes do not have adverse effects on productivity.) Although radicals may be unwilling to wait a generation for the major effects to take place and prefer instead a revolution to accomplish redistribution aims, the destruction of capital and confusion following such events might lead to a situation where average income would be considerably lower and income not much more equally distributed than if mundane and undramatic redistributional taxes had been used instead.

C. The Impact of the Elasticity of Substitution

Up to now the results are based on a Cobb-Douglas production function which

has an elasticity of substitution of unity. Since we have growth in the system, this assumption may have some impact on the results and a series of simulations were run using the *CES* function that has been explored by Kenneth Arrow et al.[11]

Summarizing the results in a capsule form is extremely difficult for a number of counteracting factors influenced the results: further, the results feature a number of small puzzles which are difficult to explain. For those wishing to explore these matters further, the results are presented in Appendix Tables 3 and 4.

IV. Quantitative Results: Introduction of Certain Dynamic Factors

A. The Impact of Harrod-Neutral Technological Change

If we introduce technological change such that the production arising from a given capital and labor stock is multiplied by an exponentially growing factor, per capita income grows, the capital stock grows (because savings increase), and eventually the system achieves a steady-state growth path. Using a Cobb-Douglas production function, factor income shares remain the same.

The results of the simulations can be easily summarized: the equilibrium income distributions do not seem greatly affected by the introduction of Harrod-neutral technical change. (Indeed, the only noticeable effects occur with the non-linear transfer function and these are relatively small.) Undoubtedly other types of technological change would complicate the results, but exploration of these matters must be left for future research. Results of the experiments with Harrod-neutral change are presented in Appendix Table 5.

B. The Impact of Population Change

If we now add to the analysis population growth which can arise from many different patterns of differential fertility, a large number of cases are open to explore. Simplification can be achieved once we realize that introduction of population change has two major effects: it raises the absolute value of total production; and it allows different rates of growth of the capital-labor ratio to occur through changes in the denominator of the fraction, rather than the numerator. Rather than multiply examples endlessly, it seems most useful to examine only several simple patterns of fertility in order to show how the system works. One financial constraint on this process of analysis must also be mentioned: the greater the number of people in the system, the more expensive the simulation becomes. To obtain the results reported in Table 7, I started the system with only fifty people; introduced a 10 percent population growth (per generation) and ran the system for only twenty-five generations. This led to an eightfold increase in population and, as a result, almost a quadrupling of computer cost. (It must also be noted that in order to limit population growth, "poor" and "rich" families are defined as the 20 percent of families on either end of the income distribution, while the "middle class" is the remaining 60 percent; this is slightly different than the income definitions used in calculating Appendix Table 1 below.) Equilibrium gross national products are presented in Appendix Table 6.

The most surprising result appears where the transfer function is linear: here differential fertility appears to have relatively little impact on the equilibrium distribution of income, a result which is somewhat different from the situation in Appendix Table 1 where no net capital formation takes place. In the case of the nonlinear transfer function, on the other hand, the expected impact of differential fertility can be observed in nonprimogeniture situations, i.e., the equilibrium

[11] See Arrow et al. For the derivation of factor shares I used the simple formulae derived by R. G. D. Allen.

Assumptions: Standard deviation of random element is .15; Cobb-Douglas production function with labor share of national income as 75 percent; no technological change; no income or capital redistribution; no negative transfers.

distribution appears more equal, the greater the number of children of the rich vis-à-vis other groups in the population.

It should also be noted that population growth gives rise to a somewhat more unequal equilibrium distribution of income than with no population growth and it seems likely that this effect would be greater if population growth were higher. This may be tied up with the results that with population growth, the equilibrium per capita income and the equilibrium capital-labor ratio are somewhat lower which, as a result, means that returns per unit of capital are higher and returns per unit of labor are lower. The exact interaction of these various factors is, however, complex.[12]

[12] Some insight can be gained into these matters by starting from the well-known formulas for the separation of the components of variance;

$$\mathrm{Var}(Y)=\mathrm{Var}(P)+\mathrm{Var}(W)+2\ \mathrm{Cov}(P,W)$$

and $\mathrm{Var}(P)\approx \bar{\imath}^2\ \mathrm{Var}\ (k)+\bar{k}^2\ \mathrm{Var}(i)+2\bar{\imath}\bar{k}\mathrm{Cov}(i,k)$

(over)

V. Application of the Model

Given the assumptions of the model, the numerical results obtained in the simulations cannot be directly applied to available data on the distribution of income. Certain biases resulting from the assumptions require special attention.

First, the model assumes that labor income of an individual is not positively correlated with his parents' income. Since it is generally believed that there is, indeed, a positive correlation, this means that the results presented above have a bias toward equality. In future simulations this fact could be built in the model either directly (a procedure which would require considerably more memory capacity of a computer than the program used in this study) or by using a different type of intergenerational savings function in which a fraction of the parents' income would be considered human capital transmitted to the children.

Second, the model assumes that labor income and property income are not positively correlated. Although data have not been published in a useable form empirically to investigate such matters, I strongly suspect that in the United States there is a positive correlation. Certainly those occupying important positions to which high labor incomes accrue are in a better position to invest their money in investments yielding high returns; further, the existence of great wealth often permits people to obtain positions yielding high labor incomes. If this correlation between labor and property income is positive, then the empirical results obtained with the simulation model show a greater income equality than actually exists. Repairing this fault in the model would not be difficult: labor income could be made a function of the random variable plus a given fraction of wealth.

Third, for technical reasons labor incomes in the model were bounded by limits of .5 and 1.5 of the average income, and since capital accumulation is a function of total income, certain limits are placed on the amount of capital accumulation that one individual can carry out. Since this does not permit the existence of a Henry Ford, a J. Paul Getty, or a John D. Rockefeller, who manage to accumulate enormous sums within a single lifetime, the results of the simulation model show a bias toward equality. This might be repaired in the model by designating one person in each generation who is destined to strike it rich at the expense of everyone else (who is "taxed" for this purpose).

Fourth, the distribution of income is calculated from labor and property income before family accumulation (or disaccumulation) takes place. This procedure omits a source making for greater income inequality, namely the income accruing to owners of recently accumulated wealth. In the model presented above, this should not make very much difference; but in more complicated models, this factor must be taken into consideration. On a more general level, the simulation model is based on the assumption that capital accumulation for the entire society occurs through the net addition to inherited productive capital by various families in the system. An alternative method for achiev-

---

where Y = total personal income; P = property income; W = work income, i = return on wealth; k = wealth; $\text{Var}(Y)$ = variance of Y; $\text{Cov}(i, k)$ = covariance between i and k; and a bar over a letter indicates an average value. In the case discussed in the text, $\bar{i}^2$ increases, $\text{Var}(k)$ remains the same, the $\bar{k}^2\text{Var}(i)$ factor still remains zero (since there is no variation in return per unit of capital) and the covariance term remains roughly the same. Thus the overall variance in property income rises and this, in turn, leads to an increase in the variance of overall personal income. Certain other puzzling phenomena remain, particularly in the data for the non-linear savings function; these are due in part to the fact that unlike most other simulations in this essay, equilibrium was achieved extremely slowly and often by the twenty-fifth generation (the cutoff point), this equilibrium point had not been reached.

ing economic growth that does not involve inheritance occurs when claims on productive capital are accumulated through part of a person's lifetime and then are converted into consumption by the end of the person's life. If generations overlap and if the maximum accumulated wealth is greater for each succeeding generation, then societal capital accumulation could occur without any inheritances.[13] Although such extreme a situation does not seem very likely, such a process may be occurring in part and the equilibrium income results of the simulation model would have a further bias toward equality. This factor could be incorporated into the model, but considerably more memory space in the computer would be required.

Fifth, in the simulation model factor incomes are distributed according to the marginal productivity theory. This is not, however, a crucial aspect of the model since by substituting different coefficients in the production function one can easily change the share of income received for the services of labor and capital. Although I have not considered any interactions between relative factor shares and some of the other parameters of the system (on the grounds that no convincing evidence of such a relationship has been found), such an effect could easily be incorporated into the simulation.[14]

Sixth, the model is allowed to run to equilibrium which, in many cases, takes twenty or so generations. Much more useful for policy purposes would be examination of situations where, starting with the current size distribution of income and wealth, the model were allowed to run only for several generations. The purpose of letting equilibrium be achieved is to give some general results about the direction of change that may be of use to analysts facing many different size distributions of income and wealth.

Seventh and finally, our knowledge about the actual parameters of the system that would influence the equilibrium size distribution of income and wealth is quite limited. Most importantly, we have no statistical idea about the shape of the intergenerational savings function which proves such a critical factor in determining the final equilibrium positions. We do not know the relative importance of more complicated inheritance arrangements where wealth is passed two generations away through particular types of trust arrangements. Our quantitative notions about marriage patterns and inheritance rules may be greater, but such matters still need considerable quantitative analysis before parameters can be derived for use in the model. Except for some imaginative work by Robert Summers, little work has been done on calculating lifetime size distributions of income.[15] Thus, even if the simulation model were more sophisticated, we would not have the requisite knowledge of the proper parametrs for running the model for predictive purposes.

VI. Some Speculations

Although the simple simulation model has some obvious shortcomings and must be viewed as a starting point for more sophisticated models, the results obtained point toward a number of factors neglected by economists interested in the size distribution of income. Moreover, the results permit several different answers to some puzzling questions regarding changes in the degree of inequality of the size distribution of income over time.

Among Western non-Marxist economists there seems to be some agreement that the distributions of income and wealth

[13] Such a situation is explored by James Tobin.

[14] I would like to thank Steven Resnick for his ideas on this theme.

[15] Lifetime income distributions in the United States are estimated by Summers. I would like to thank him for sending me a copy of this extremely useful study.

of nations become increasingly unequal during the early stages of the development process but that after the development process is well underway, this distributional tendency is reversed and the income distribution becomes increasingly more equal. Certain empirical evidence supports this proposition. For instance, in the United States estimates of the distribution of wealth show an increasing inequality throughout the ninteenth century, reaching a high point at the turn of the century. Since then, however, these data show that the inequality of wealth holding has declined so that the Gini coefficient of wealth inequality was roughly the same in 1962 as in 1860.[16] In this century the inequality of personal wealth holdings appears to have decreased in the United Kingdom as well.[17] Finally, income inequality has decreased in a great many developed nations in the last 30 to 60 years and there appears to be an inverse relationship in the West between the level of development and the Gini coefficient of income inequality on both a time-series and a cross-section basis.[18] A number of theoretical arguments concerning the causes of such shifts in the distribution of income have been offered[19] and in this digression I would like to add one additional explanation based on the simulation results above.

In a highly underdeveloped nation the major source of wealth is land; inheritances consist primarily of intergenerational transfers of a fixed amount of land; and the equilibrium distribution of income in such a case is described in Section II. As industrialization begins and accumulated industrial capital becomes an important source of wealth, it seems likely that the intergenerational transfer function approaches the non-linear form described in Section III. This is because the biological level of subsistence is still a substantial proportion of average income and it is unlikely that people with relatively low incomes could pass on a very significant proportion of their lifetime income to their heirs. As per capita income rises, this biological subsistence income becomes an increasingly smaller share of average incomes and it seems likely that the income level below which no intergenerational transfers take place does not rise as fast as average income. If so, then the non-linear intergenerational transfer function asymptotically approaches the linear case.

In such a situation, three stages in the distribution of wealth and income can be distinguished: a stagnant stage in which the distribution of wealth and income remain relatively constant; the initial stages of industrialization in which the distribution of wealth and income become increasingly more unequal (under the impact of a non-linear intergenerational savings function); and a later stage of industrialization in which the distribution of wealth and income become more equal when the intergenerational transfer function becomes more linear.

Since we know very little about intergenerational transfers at any stage of development, this scenario of development

[16] For relevant data see Lee Soltow, Robert Lampman, and James Smith.

[17] Data are presented by Lampman, p. 214.

[18] The four most extensive recent international comparisons of the size distribution of income are by Simon Kuznets, Irving Kravis, Harold Lydall (who only covers labor income), and Richard Weisskoff.

[19] Kuznets (1955) focuses on the shift from rural to urban areas as the most important casual factor. (This model is investigated more throughly on a theoretical level by Henri Theil, and on an empirical level by Weisskoff.) Stiglitz bases an explanation for the same phenomenon on the relationship in the process of economic growth of the starting point to the equilibrium production level. R. Albert Berry focuses on unemployment and changes in particular market imperfections. Others have focused on more politcal factors such as the increase of political mobilization accompanying economic development that leads to greater progressive redistribution of income and wealth by the government after a particular point of development.

must remain speculative; nevertheless, it does provide a focus for future empirical research.

VII. Two General Conclusions

A great many different cases have been discussed, and these are but a small fraction of the possible cases that can be generated by the model. Nevertheless, two general conclusions can be drawn:

First, for a general theory of the size distribution of income, we must take into account the influence of the size distribution of wealth; and this means we must bring into the analysis a number of important social and economic variables such as the pattern of intergenerational transfers of income and wealth, the rules of inheritance in the society, and differential patterns of fertility of income classes. It is impossible to generalize about long-run changes in the size distribution of income and wealth in capitalism without specifying many more variables than economists have usually done. Blanket predictions about increasing concentration of income and wealth, for example, the orthodox Marxist analysis of such problems, implicitly make too many vital assumptions to be of much use.

Second, the simulation model presented in this paper provides a starting point for such a broader type of analysis of the distribution of income and wealth. In order to bring the analysis closer to actual situations in particular countries, much more empirical and theoretical work needs to be done. On the theoretical side, we need to consider many more complications than those presented in this essay; on the empirical side we need to have a much clearer picture of the critical parameters. The model does, however, point to one extremely important factor—the shape of the intergenerational savings function—which has been neglected by previous analysts and which I hope to have demonstrated is critical in predicting changes in the size distribution of income and wealth.

Appendix

Determination of the Speed of Convergence to an Equilibrium Income Distribution

Due to the influence of random factors in the inheritance-marriage simulation program, the generated income distribution does not completely converge to a single income distribution, but rather to a band of income distributions around the equilibrium. A number of curve-fitting methods were attempted in order to derive the equilibrium distribution but these proved unsatisfactory and the following alternative method was adopted. This is a modification of a method suggested by Richard N. Cooper, to whom I would like to express my thanks.

First, an unweighted average and standard deviation of the Gini coefficient of income equality were calculated for the last five generations in the thirty-generation simulation. The sixth to last Gini coefficient was then tested to see if it fell within the .95 confidence limit of the calculated average. If this was the case, then the unweighted average and standard deviation were recalculated to include this datum and the next Gini coefficient was examined in a like manner. This process was stopped when the examined coefficient did not meet the test; the number of generations was then determined, and average coefficient for the other indicators of inequality (for example, the standard deviation of the logarithms of income, the share of income accounted for by the top 10 percent, etc.) were recorded.

Then, with the calculated standard deviation of the Gini coefficient from the above process, I started from the first generation to see at what generation the Gini coefficient had a significant chance of belonging to the calculated equilibrium. When this point was reached, the generation number was recorded. The conversion point was considered to lie between this point and the earliest generation to be included in the calculation outlined in the first step.

Such a procedure is based on the assumption that the income distribution converges by and large within thirty generations. Whether such a convergence occurred at all was determined by visual inspection of the entire series of calculated Gini coefficients.

APPENDIX TABLE 1—GINI COEFFICIENTS OF EQUILIBRIUM INCOME DISTRIBUTIONS ASSUMING DIFFERENTIAL FERTILITY RATES[c]

Number of children[a]			Marriage Rules

Primogeniture			.310	.306	.300
Compromise			.306	.305	.295
Equal division			.308	.302	.295
3	1	3			
Primogeniture			.310	.306	.303
Compromise			.168	.160	.135
Equal division			.168	.158	.130

Assumptions: No net family capital formation; no capital or income redistributions; standard deviation of random element is .15; labor share of national income is 75 percent.

[a] The poor are those 25 percent of families with the lowest income; the rich are those 25 percent of families with the highest incomes.

[b] If the system starts from a highly unequal distribution of wealth, the equilibrium distribution of income is equal to its original value. If the system starts from a relatively equal wealth distribution where high ability people with no property might marry low ability with property (since they would be next to each other on the income scale), then the equilibrium income distribution would be highly equal.

[c] A Gini coefficient of zero represents total equality; a coefficient of unity represents total inequality.

The Production Lag

By JOHN A. CARLSON*

Ascertaining the nature of the transmission and diffusion of economic adjustments and of the speed with which they occur offers a host of perplexing problems. We shall focus here primarily on one such problem: finding the production lag or period of time from which production is begun on an item until it emerges from the productive process as a finished good. The emphasis will be on the use of accounting data to determine the length of this lag and its relation to other data reported about manufacturing industries.

The sequel is as follows. Section I develops a production-period formula; Section II explores the relationship between the production period and whether an industry produces primarily to order or to stock; Section III adds considerations of the average delivery period; Section IV investigates a conjecture by Charles Holt and Franco Modigliani about variations in the production period; Section V, with distributed lead estimates, attempts to obtain more information than the industry data appear willing to reveal; and Section VI is a summary of the main results.

I. A Production-Period Formula

Discrete counterparts to the continuous relationships presented here may be found in Holt and Modigliani, pp. 35–40. For notation, let

x = the production period

$q(t-u+x)$ = rate of production of finished goods at time $t-u+x$

$w(t, t-u)$ = work-in-process at time t of items whose production began at time $t-u$

$m(y)$ = rate of materials added per unit of goods in production for a length of time y

$v(y)$ = rate of value-added per unit of goods in production for a length of time y

W_t = total stock of work-in-process at time t

The gross value of production of finished goods equals total materials used and total value-added. Thus, for one unit of output:

$$\int_0^x [m(y) + v(y)]dy = 1 \tag{1}$$

We can also write

$$\begin{aligned} &w(t, t-u) = q(t-u+x) \int_0^u [m(y)+v(y)]dy \\ &\text{for } 0 \leq u \leq x; \text{ and} \\ &w(t, t-u) = 0, \text{ otherwise} \end{aligned} \tag{2}$$

The integral can be thought to represent the percentage completion after time u in production. This percentage multiplied by $q(t-u+x)$, the rate of finished production that will occur at time $t-u+x$, gives $w(t, t-u)$, the corresponding level of in-process stock at time t. Then, integrating over all levels of work-in-process yields the total stock of work-in-process at time t:

$$\begin{aligned} W_t &= \int_0^x w(t, t-u)du \\ &= \int_0^x q(t-u+x) \int_0^u [m(y)+v(y)]dy\, du \end{aligned} \tag{3}$$

Work-in-process inventories thus depend on future output, the rate at which materials and value-added are inserted into the

production process, and the production period. Data are available on work-in-process inventories and on production. If we knew or could assume something about the rate at which goods-in-process are written up in value, we could infer a value for the production period x.

In the empirical estimates below, a month will be taken as one unit of time. Production of finished goods for the month ending at time $t+1$ will be:

$$P_{t+1} = \int_t^{t+1} q(z)\, dz \tag{4}$$

Consider a stationary situation in which $q(t-u+x)$ is a constant q. In that case, monthly production $P_{t+1}=q$. If we also assume that $m(y)$ and $v(y)$ are constants, then from (1), $m+v=1/x$. Making this substitution in (3) and assuming production is constant yields the following when (3) is integrated out: $W_t=qx/2$. Substituting P_{t+1} for q and solving for x, we have

$$x = 2W_t/P_{t+1} \tag{5}$$

Equation (5) was anticipated by Moses Abramovitz, whose interest in the timing of cyclical turning points of inventory components led him to this technique for estimating the production period.[1]

Figure 1a depicts our assumptions graphically. Future production is assumed to remain constant at level P_{t+1}. The total area of the two triangles A and B represents W_t, total stock of work-in-process

[1] This concept of the production period differs in two respects from that associated with the Austrian measure of the roundaboutness of a productive process as explained by Bohm-Bawerk, pp. 78–91. First, we take fixed capital as given and evaluate the time within manufacturing plants of transforming inputs into finished goods; Bohm-Bawerk includes in the figure for the period of production the time taken to produce the fixed capital as well. If one were interested and had enough information about the productive relationships, the Austrian figure could be pieced together from the figures obtained by the approach taken here. Second, Bohm-Bawerk takes a mean of the time from various labor inputs until final output, whereas we assume a steady accretion of value-added from the beginning of a particular productive process and compute the overall time from start to finish. Geometrically, our production period corresponds to the base of a triangle and his to approximately half the base (ignoring the time to produce fixed capital).

inventories at time t, and the height of the line at $t-u+x$ represents $w(t, t-u)$. The area of the triangle A is the total materials tied up in work-in-process inventories, and B is the corresponding value-added.

Equation (5) provides a rough first approximation for the production period. How good an approximation it is depends on the relevance of many of the assumptions used. Some considerations suggest that x computed from (5) will overstate the actual production period and others that x will be too low. For example:

1). If most materials enter at the beginning of the productive process, instead of evenly throughout, then equation (5) overstates the production period. The extreme case of all materials being added at the start of the process is depicted in Figure 1b. Remember that W_t (the area of A and B combined) and P_{t+1} are given and that x is to be determined. Abramovitz, p. 174, has also pointed out this possibility.

2). If a portion of value-added is a markup that enters into the gross value of production when the items become finished goods but not into the estimates of work-in-process inventory, then equation (5) underestimates the production period. This is depicted in Figure 1c. Again x must be adjusted so that area of A and B combined is the same as in Figure 1a.

3). If production is growing along a linear trend, then $2W_t/P_{t+1}$ will underestimate x slightly if x is less than 1.5. The reverse holds for declining production.[2]

4). There may be "stages" of processing between which work-in-process stocks are temporarily stored. In such cases, equation (5) will underestimate the production period if most of the processing occurs at the later stages.[3] Other things equal, of course, the longer the wait between stages, the longer will be the overall production period.

Formula (5), to repeat, is only a rough approximation, subject to vagaries of accounting systems and peculiarities of different productive arrangements. However, it does give some indication of the order of magnitude of the production period in varying industries and the numbers presented below do have an intuitive plausibility. Perhaps more experienced observers of manufacturing operations can verify or cast doubt on this initial impression.[4]

Data on work-in-process inventories and levels of production are available from the Bureau of the Census. The Annual Survey of Manufactures provides year-end stocks of inventory by stage of fabrication as well as cost of materials consumed and value-added in manufacture for two, three, and four-digit industries.

Monthly data on inventories are also available for two-digit industries. Only a few of these published series show inven-

[2] This result follows from assuming that production changes at a linear rate r per period:

$$q(t-u+x) = q(t)[1 + r(x-u)]$$

In that case from (4):

$$P_{t+1} = q(t)(1 + r/2)$$

and from (3), with the assumption that $m(y)+v(y) = 1/x$:

$$W_t = q(t)(3x + rx^2)/6$$

Then

$$\frac{2W_t}{P_{t+1}} = \frac{x(3 + rx)}{3 + 3r/2}$$

which for positive r is greater than x if x is greater than 3/2.

[3] To see this for the two-stage case illustrated in Figure 1d, let b = time between stages, s = time to complete the first stage and x = total production period. Actual processing time is $x-b$. Either by integration or by direct computations of areas in the figure, we have

$$W_t = [(x-b)/2 + sb/(x-b)]P_{t-1}$$

Rearranging terms

$$\frac{2W_t}{P_{t+1}} = x + b\left(\frac{2s}{x-b} - 1\right)$$

Therefore, $2W_t/P_{t+1}$ is less than x if the first stage is completed in less than half the actual processing time, i.e., if $s<(x-b)/2$.

[4] I have used accounting data from a bag manufacturing plant and found that the resulting estimate was very close to the production manager's guess as to the length of the production process in the plant.

tories by stage of fabrication, but monthly Census data have been prepared for all two-digit industries from 1953 to 1966 by David Belsley, who has generously made these data available. For a description of the data see Belsley's book.

II. Production Periods and the Stock-Order Dichotomy

In a study of the German leather and shoe industries T. Thonstad and D. B. Jochems write, "... we may reasonably assume that the tanners are more engaged in production for stock building than are the shoe manufacturers, since their period of production is so much longer" (p. 143). Before considering their implicit hypothesis about stocks and the production period we shall examine whether or not our formula using *U.S.* data reveals a longer production period for tanners than for shoe manufacturers.

Industry 3111, Leather Tanning and Finishing, and industry 3141, Footwear, Except House Slippers and Rubber Footwear, should correspond reasonably well with the two industries Thonstad and Jochems studied. We considered data for 1964–1966 from the Survey of Manufacturers. For each year average monthly production was set equal to the sum of cost of materials consumed and value-added, adjusted, divided by 12. We added the end-of-year work-in-process inventories for the current and previous years and then divided this figure by average monthly production to get an estimate of the production period. The results in months are as follows:

	Industry 3111 Tanning	Industry 3141 Shoes
1964	1.84	.54
1965	1.76	.53
1966	1.68	.54

The figures suggest that tanners have a production period about three times as long as the one for shoe manufactuers. We cannot tell to what extent there is a seasonality in year-end inventory that might distort the results. For industry 31 as a whole there is no evidence of a notable year-end change in W_t, but this does not tell us much about industries 3111 and 3141. The estimates, however, are definitely consistent with Thonstad and Jochem's observation that tanners have a much longer production period than shoe manufacturers.[5]

Is it plausible to expect that the length of the production period would be related to the extent to which an industry produces for stock rather than to order? In the quoted passage, Thonstad and Jochems seem to imply that the longer the production period, the more there is production to stock. The decision about which way to organize production is likely to depend on the relative costs of holding inventories versus costs of backlogging orders. (For example, see Holt et al. or Carlson and T. B. O'Keefe.) In the case of a reasonably standardized product like leather, the potential cost of having unsaleable stock is not so great as in an industry such as shoe manufacturing where styles may become obsolete. Thus, any tendency for tanners to produce more to stock than shoe manufacturers may be attributable to such relative costs rather than to the length of the production period.

In a world of certainty, the production period should have no relationship to the stock-versus-order distinction. Except for considerations of efficient batch size or production-smoothing, there should be neither stocks of finished goods nor unfilled orders. Production can be begun

[5] Ruth Mack, for illustrative purposes, suggests a two-month period for shoe leather and a one-month period for upper leather when constructing a "minimum service" stock for tanners, p. 192. Our estimates for the tanning industry are clearly of the same order of magnitude.

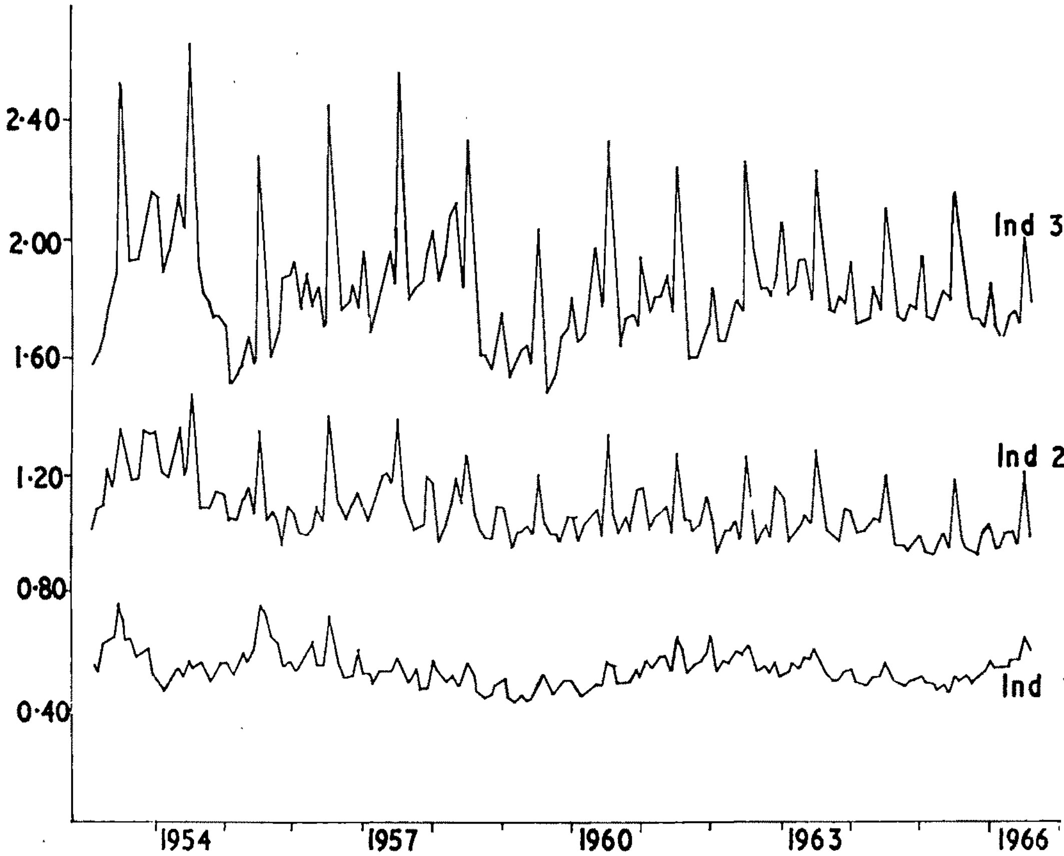

FIGURE 2. MONTHLY CALCULATIONS OF $2W_t/P_{t+1}$ FOR INDUSTRIES 27, 22, and 36.

sufficiently in advance so that finished goods will be ready precisely when demanded. In a world of uncertainty, as noted before, whether production is in anticipation of demand or in response to demand depends to a large extent on relative expected costs. If items that have long production periods are generally complicated and built to varying specifications, then they will also tend to be produced to order. Thus there may be an empirical relationship between the production period and the relative size of unfilled orders that is not intrinsically a result of the length of the production time.[6] However, if orders are backlogged, then the longer the production period, the longer we would expect the delivery period to be.

[6] For a recent discussion of reasons for having unfilled orders, see Gerald Childs who also summarizes some of Abramovitz' ideas on the subject.

The production period for two-digit industries can be estimated from two different sets of data. With Belsley's data, not seasonally adjusted, the ratio $2W_t/P_{t+1}$ in each industry has been computed for every month from February 1953 to August 1966. For illustrative purposes, the results for three industries are graphed in Figure 2. The arithmetic mean of the production period in each industry for each full year 1954 to 1965 has also been computed. The figures for 1965, with the sample standard deviation of the mean in parenthesis, are shown in column 2, Table 1. Alternatively, data from the Survey of

[a] Computed from Annual Survey of Manufactures, 1966, General Statistics for Industry Groups and Industries, and Value of Manufacturers' Inventories.
[b] Computed from M3 Monthly Survey data by the Bureau of Census, data prepared for David Belsley. Columns (3), (4), and (5) from same source.
[c] See text for method of calculating delivery periods.

Manufactures yield the estimates shown in column 1. The two sets of estimates are similar.

The first thing to note is that there is no strict dichotomy separating the average production period of industries with unfilled orders from those without. There is evident overlapping.

It is also apparent that on balance, industries without unfilled orders do tend to have lower production periods. We can check this observation by performing a median test as described by S. Siegel, pp. 111–15. An industry is classified according to whether or not it has unfilled orders and whether its estimated production period is above or below the median for all industries. The following array results with the figures from column 2 of Table 1:

	Industries without unfilled orders	Industries with unfilled orders	Totals
Production period equal to or above median	1	9	10
Production period below median	5	4	9
Totals	6	13	19

For 1965, industry 23 has the median production period. This has been included in the upper part of the array in order to get the greatest probability of finding this or a more extreme distribution on the assumption that both categories have the same median. This probability is slightly less than .05. Since in every other year, as well as with column 1 figures, all six indus-

tries without unfilled orders have production periods below the combined median, we reject the hypothesis of a common median and tentatively claim that industries without unfilled orders do tend to have shorter production periods.

III. Delivery Periods and Stock-Versus-Order Production

Consider next the overall reaction time within manufacturing industries and how the production period influences its length. Assume initially that custom, technology, and least-cost considerations have determined whether an item is produced to order or to stock. The reaction time can then be analyzed for each situation separately.

Production to Order

When production is to order, the initiating signal for a manufacturing firm is a new order. The length of time from receipt of the order until shipment to fill the order is called the *delivery period* or lead time.

It is convenient for us to divide the delivery period d into three phases: waiting time, incubation time, and accumulation time. These are depicted in Figure 3a. The waiting time w, from t_0 to t_1, is the interval from receipt of the order until the beginning of its production. The incubation time from t_1 to t_2 is the production period x. Finally, there may be an accumulation time c from t_2 to t_3 in which an order is completed. Thus

$$d = w + x + c \tag{6}$$

The delivery period undoubtedly depends on capacity constraints. If capacity is fully utilized when an order arrives, then the initiation of production must wait. The larger the backlog of orders relative to capacity, the longer will be the waiting time w. The accumulation time c may also be affected by capacity constraints. With excess capacity, several items for an order

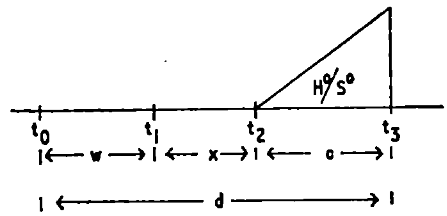

FIGURE 3a. PRODUCTION TO ORDER

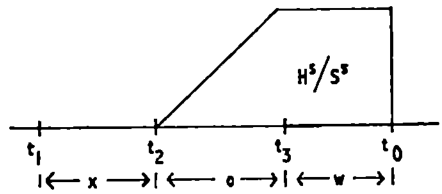

FIGURE 3b. PRODUCTION TO STOCK

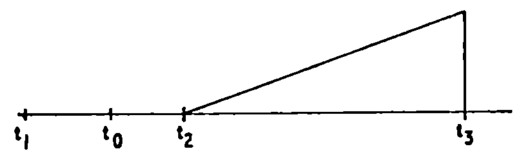

FIGURE 3c. MIXED CASE

FIGURE 3. GRAPHICAL ILLUSTRATION OF AVERAGE FINISHED INVENTORY PER UNIT OF SHIPMENTS.

t_0 = TIME ORDER IS RECEIVED
t_1 = TIME PRODUCTION IS STARTED
t_2 = TIME FINISHED GOODS START TO ACCUMULATE
t_3 = TIME PRODUCTION IS COMPLETED ON THE LOT

may be produced simultaneously while with tight capacity the items may be worked on sequentially and the accumulation time strung out.

The size of each order can also influence the accumulation time. If each order is for a single item, there will be no accumulation time. With many items in an order, the manufacturer may accumulate the entire order before shipment and hence hold inventories against backlogged orders. Abramovitz, p. 404, has estimated that such stocks comprise 15–25 percent of all finished goods in manufacturing industries.

Suppose finished goods flow out of the manufacturing process at a uniform rate and that as soon as one batch of items is shipped another begins to accumulate. In such a case, the average stock of inven-

tories per unit shipped is:

$$(7) \quad H^0/S^0 = c/2 = (d - x - w)/2$$

where H^0 denotes finished inventories held for unfilled orders and S^0 shipments to fill unfilled orders. This formula is depicted in Figure 3a where the height of the triangle is one unit.

Production to Stock

When production is to stock, the initiating signal occurs when production begins. There is again an incubation period, before finished goods are completed, and an accumulation period. The waiting period, however, comes at the end while the items await an order.[7] If shipment occurs immediately upon receipt of an order, the average stock of finished inventories per unit shipped is

$$(8) \quad H^s/S^s = w + c/2 = (d - x + w)/2$$

where S^s denotes shipments from stock and H^s the corresponding stock. Formula (8) is depicted in Figure 3b. The term d denotes the delay from initiation of production until shipment and is analogous to the delivery period but its duration is not so readily estimated from available data.

The Delivery Period

Victor Zarnowitz, p. 16, has suggested that the ratio of unfilled orders to shipments, in the absence of any better measures, may be used as a crude indicator of an industry's average delivery period. With available data there is no way of knowing what proportion of shipments go to fill backlogged orders and what proportion is out of stock. Zarnowitz's indicator, however, is in a sense independent of these proportions. To see this let

S = total shipments during a period
U = unfilled orders at the beginning of the period
r = proportion of S that fill backlogged orders ($r = S^0/S$)

Assuming r and S are reasonably steady, then U/rS is the average delivery period for items produced to order. The average delivery period on the rest of the shipments is zero, ignoring response time in filling orders from stock. If these two delivery periods are averaged by assigning a weight r to U/rS and weight of $1-r$ to 0, the average is evidently U/S. With monthly data, this indicator, if greater than one, could be refined a bit more by using shipments in subsequent months, but for our purposes this refinement is not essential. Thus, the figures labelled Average Delivery Period in Table 1 are obtained by dividing the sum of unfilled orders in an industry from December 1964 to November 1965 by the total shipments during 1965.

With our rough estimates of the production period and the delivery period, we can investigate the possibility in industries reporting unfilled orders that *all* production is to order. The figures for d and x in Table 1 immediately rule out such a possibility for industries 27 and 38, for if all production is to order, then d must be at least as large as x. To obtain the average delivery period just for items produced to order, the relevant ratio is U/S^0. In industries 27 and 38, the proportion of production for stock must be at least 55 and 12 percent, respectively, if the delivery period on items produced to order is to be no shorter than the average production period.

Equation (7) can be used to examine whether finished stocks in industries with unfilled orders could be the result of pro-

[7] As a referee has suggested, there are undoubtedly prior considerations, such as desired inventory-to-sales ratios, that determine the planned rate of production. Variations in the average waiting time would then depend in part on the ability of decision makers to recognize the relationship between the planned and the actual situation.

duction to order or whether they result primarily from production to stock. Consider Figure 3a. We have estimates of d and x but not of w and c. Given d and x, the smaller is w, the larger is c, and hence, the larger is H^0/S^0. Subject to a qualification below, we can put an upper limit on H^0 by assuming that all production is to order and that w is zero. In such a case, from equation (7), H^0/S^0 becomes $(d-x)/2$. These figures are shown in column (5) of Table 1.

If $(d-x)/2$ is viewed as an upper limit on the ratio of finished stocks to shipments when production is entirely to order, it becomes apparent when comparing columns (3) and (5) of Table 1 that in industries 22, 24, 25, 26, and 31 there must be a substantial amount of production to stock. Similar interpretations hold for industries 32–35 although in these industries a larger portion of the finished stocks could be the result of accumulation of goods produced to order. Only in industry 36 and most notably in 37 does $(d-x)/2$ exceed the actual ratio of finished inventories to shipments. Without more direct information, it seems believable from these figures that most production in industry 37 is to order. If so, with a ratio of finished stocks to shipments of .19, the implied value of waiting time w is 1.97 months and of accumulation time c is .36 months.

Unfortunately, this is about as far as this approach can go in separating shipments into their stock-versus-order components. In each industry, except possibly 37, there is undoubtedly production to stock. However, even if we had a guess as to the size of H^s, we cannot use equation (8) to determine S^s without more information about the values of x, c, and w for items produced to stock. Such a wide range of values is plausible that almost any proportion $r=S^0/S$ from 0 to 1 could be obtained.[8]

Belsley for computational convenience assumes that $H^0\equiv 0$, but stresses in a footnote that this is not to be taken as a behavioral hypothesis, p. 62. We question the assumption for industry 37 and it may not be a very good approximation for industries 32–36. In the remaining industries it appears to be readily justifiable. Column (5) of Table 1 was intended to give the maximum H^0/S on the assumption that all production was to order. H^0 may thus be considerably lower than the numbers indicate. There is, however, another possibility shown in Figure 3c. Production may begin prior to receipt of an order and then completed to specification after the order is received. In this case the delivery period would be from t_0 to t_3 but the accumulation period could be much larger than $d-x$ and thus H^0/S could be larger than $(d-x)/2$. Without more information little else of substance can be said on the relevance of Belsley's assumption that $H^0\equiv 0$.

Since the production period is one component of the delivery period, we would expect to find a positive association between the two. To check this hypothesis, the industries with unfilled orders were ranked by size of production period and by size of delivery period. The Kendall rank correlation coefficient is .67, which is highly unlikely under the null hypothesis of no association. The t-statistic is equal to 3.[9]

IV. Changes in the Production Period

Holt and Modigliani discuss three types of productive processes. They are:

[8] Belsley, using a different approach, was also unable to determine how much of the industry aggregates fell into each of these two categories even though he did finesse the problem ingeniously. He later commented: "It is not too surprising, although disappointing, that we are unable to unravel from these few short-run parameter estimates enough information to put back together what was never there in the first place" (p. 146).

[9] The computational procedure for obtaining these statistics is presented by Federick C. Mills, pp. 312–17.

Type A: Production time decreases as rate of production is increased
Type B: Production time is not affected by rate of production
Type C: Production time increases as rate of production increases

They suggest that the "... type C form of operation is the most general and perhaps the most common one" (p. 40). With our estimates of the production period, we can examine this conjecture, although it should be borne in mind that by construction, the estimate of the production period is likely to fall as production rises since production is in the denominator. If the reverse holds, we would interpret such a result as strong confirmation of Holt and Modigliani's conjecture.

A cursory inspection of our production period over seasonal fluctuations gives a strong impression that most industries behave in accordance with type A, but this may be the result of the manner in which the production period is computed.

An alternative approach is to examine the relationship between $\Delta P/P$ and $\Delta W/W$ where it is understood that the percentage change in W is taken one period earlier than the corresponding percentage change in P. The following equation then holds approximately

$$\frac{\Delta x}{x} = \frac{\Delta W}{W} - \frac{\Delta P}{P} \tag{9}$$

where x is the production period as estimated by equation (5).

Suppose there is a linear relationship between the percentage changes in P and W:

$$\frac{\Delta P}{P} = a_1 + b_1 \frac{\Delta W}{W} \tag{10}$$

Substituting in (10) for $\Delta W/W$ from (9) and solving for $\Delta x/x$ yields:

$$\frac{\Delta x}{x} = -\frac{a_1}{b_1} + \frac{(1 - b_1)}{b_1} \frac{\Delta P}{P}$$

If in estimating equation (10), we find that b_1 is greater than 1, then we have evidence that x and P move inversely and that production is of type A.

If b_1 is less than 1 we cannot immediately conclude that production is of type C. It may be that the relationship is not sufficiently close to conclude anything. However, we can reverse the regression and estimate

$$\frac{\Delta W}{W} = a_2 + b_2 \frac{\Delta P}{P} \tag{11}$$

If b_2 is greater than 1, then we could say that production tends to be of type C.[10]

The results of estimating equation (10) for each manufacturing industry over the period 1953–66 are shown in Table 2. There are three industries (22, 35, and 37) which given an indication that production is of type A in that the coefficient b_1 is greater than 1.

With the other regressions none of the b_2 coefficients was greater than 1. These are not reported but can be calculated from the entries in Table 2 by using the relationship $b_2 = b_1 s_2^2/s_1^2$ where s_1 and s_2 are the standard deviations of $\Delta P/P$ and $\Delta W/W$, respectively. With the exception of industries 20 and 29, the s_1 and s_2 figures indicate that reported production tends to vary relatively more than reported work-in-process inventories. Except for the two cases noted, b_2 is smaller than b_1 and in those two cases b_2 is not appreciably greater than b_1. Although there are only three industries for which we are prepared to rule out the possibility that production is primarily of type C, there is certainly no real support for Holt and Modigliani's conjecture that type C is the most common form of operation.[11] As noted above both

[10] Because of the aggregative nature of the data, we have not formulated this as a precise problem in hypothesis testing but rather as a tentative exploration.

[11] There may be a semantic difficulty here. With stages of work in process, our measure of the production

[b] Standard deviation of $\Delta W/W$
[c] t-statistic for the estimate of b_1

the waiting time and accumulation time are likely to increase as production levels get closer to capacity; but if anything the evidence suggests that individual items get completed more rapidly.

In 18 of the 19 industries, there are positive b coefficients. In 11 cases, these are significantly different from zero at a .95 confidence level. The column headed t_b gives the t-statistics for the b coefficients. Thus, production does tend to vary in the same direction as work-in-process stocks at the end of the previous month. This suggests taking a closer look at the relationships between W and P.

period would become shorter if there were less time between stages. If by production time, Holt and Modigliani are referring to something like actual processing time, $x-b$ in Figure 1d, then the aggregate data cannot be used to determine what happens. If they mean x, the production period as we have developed the concept, then there is definitely no evidence of type C operations in the two-digit industry data.

V. An Attempt to Extract Additional Information From the Data

Formula (3) in Section 1 indicates that work-in-process stocks are a distributed-lead function of future production. Thus, a regression of work-in-process at the end of month t (W_t) on production in future months ($P_{t+1}, P_{t+2}, \ldots$) might be able to pick out roughly the extent to which work-in-process is written up as a function of the time until completion of production.

We tried regressions using nonseasonally adjusted data with a variety of lead relationships.[12] The general conclusion, with these data at the level of two-digit industries, is that variations in future produc-

[12] These were run by Robert Meyer, who has developed a working computer program to estimate distributed leads and lags using frequency domain relationships. I am indebted to him for overseeing the actual computations and for helping to interpret the results. The technique requires putting no a priori restrictions on the relationships among the coefficients. For additional information, see the cited papers by Thomas F. Cargill and Meyer.

[a] Estimates of b^* and c^* are predicted coefficients on basis of assumptions used in constructing average production period. See equation (5) in text.
[b] Ratio of coefficient b to its standard error.
[c] Ratio of coefficient c to its standard error.

tion do not explain much of the variations of work-in-process. Table 3 presents the results when it is assumed that current work-in-process is determined by production in the following two months.

The columns labelled b^* and c^* were prepared as if the assumptions used in constructing the production-period formula $x = 2W/P$ all held. That is, if production takes precisely a length of time x and work-in-process is written up linearly over the entire period, then it is possible to predict what values the coefficients will take. In industries in which the average production period is less than a month, the predicted value of b was taken to be average work-in-process $\overline{W}$ over average production $\overline{P}$, the averages taken over 163 monthly observations. When according to the formula the average production period is more than a month, the ratio $\overline{W}/\overline{P}$ was allocated to future months by the proportion of the work-in-process triangle, such as in Figure 1a, that falls in each of the future months. This accounts for the entries in the column c^* for industries 33–38.

The regression coefficients b reported in Table 3 are all much lower than the coefficients that would arise if all the assumptions behind the production-period formula held. All but two of the coefficients are positive and thirteen of them are significantly so (i.e., the ratio of the coefficient to its standard error is greater than 2). The results for c are more erratic, as were the coefficients for other values of P in the various distributed-lead regressions that were run.

While there is some association of the sort predicted, we are left with the impression that the regressions have not picked up the full relationship that probably exists between work-in-process and future production. At this point we can only offer

a number of conjectures as to why.

1. The accounting records may not be kept with sufficient precision.

2. There are a number of reasons, cited by Thomas Stanback, Jr., pp. 95–99, why production data will neither be coincident with, nor lag behind work-in-process by a given amount with any regularity. One of the more important possibilities is that there may be considerable variation in levels of goods in process between stages of fabrication. As orders increase, a number of semifinished items could be finished rapidly so that it is possible to have, in the short run, a negative relation between goods in process and production of finished goods.

3. There are undoubtedly serious problems of aggregation. For one thing, firms with very different production times are included in the same industry. More importantly one manufacturing plant's variations in production and work-in-process might offset another's variations in ways that in the aggregate could mask or distort the link between the series that might exist for each plant separately.

The empirical importance of these aggregation effects could be determined only with reliable data from a variety of manufacturing plants, perhaps from those that comprise the sample from which the aggregates themselves have been constructed. With access to such data, it might be possible to ascertain more about the distribution of production periods and the appropriate assumptions about the relationship between work-in-process stocks and production in different industries. Lacking access, we must arbitrarily assume the relationship as we did in making the rough estimates of the average production periods in each industry.

We also ran regressions between production and new orders with the intent of determining whether or not there were any consistent lead or lag relationships. The only consistent pattern, and it was very strong, was of coincident movements between the two series. There are a number of possible explanations. First, the production series is linked by construction to the new-orders series. In fact, production equals new orders minus changes in unfilled orders plus changes in finished goods inventory. Second, the data were not seasonally adjusted so that seasonal demands may be reflected in production plans geared to expected new orders before the orders actually arrive. Third, there may be effects of the sort mentioned above in which changes in between-stage goods in process may be utilized when necessary to have production conform fairly closely to new orders.

VI. Summary and Conclusions

A very simple formula has been used to estimate the production period in manufacturing industries. With these estimates, we may conclude:

1. The average production period for all two-digit *U.S.* manufacturing industries is less than a quarter of a year and for two-thirds of them it is less than one month. While adjustments in rates of production are not entirely dependent on the length of the production period, the order of magnitude of these figures provides support for incorporating, in models of inventory behavior, parameters to represent within-quarter adjustment of production rates in response to unanticipated levels of sales. See, for example, Albert Hirsch and Michael Lovell, p. 204. At lower levels of aggregation there is, of course, much greater dispersion between estimates of industry production periods.

2. Industries that report no unfilled orders and hence are presumed to produce solely to stock tend to have lower production periods than industries that have some production to order.

3. Among industries that produce to

order there is, as would be expected, a strong positive association between the length of the production period and the length of the delivery period.

4. Estimates on the production period and the delivery period can provide only limited and highly imprecise inferences about what proportion production to stock is of total production in an industry. They can be used, however, to cast doubt on Belsley's operational assumption that all industries carry finished goods only of items produced to stock. In one industry the figures suggest that there may be relatively little production to stock by the establishments reporting to the Census survey.

5. There is no evidence in support of Holt and Modigliani's conjecture that production time increases as the rate of production increases. If anything, the evidence suggests just the opposite.

These tentative results are of sufficient interest, it would seem, to justify further exploration with estimates of the production period by means of accounting data, particularly if adequate series could be utilized at a much more disaggregated level than that of two-digit industries.

The Not-For-Profit Hospital as a Physicians' Cooperative

By Mark Pauly and Michael Redisch*

The private, nonprofit hospital has usually been regarded by economists as an organizational anomaly. In particular, it has been alleged that the predominance of the not-for-profit structure within the American hospital system is associated with a weakening of the usual market constraints of competition and profit orientation. As a result, this critical element in any analysis of the medical care system in the United States has usually been modeled with a mixture of anecdote and *ad hoc* assumption. It is typically assumed that "all objectives of nonprofit organizations can be described in terms of some type(s) of output (broadly defined) or capital stock."[1] William Baumol and Howard Bowen describe these goals as "bottomless receptables into which limitless funds can be poured" (p. 497).

Model variation occurs as investigators place combinations of key variables in either the objective function or the constraint set of the hospital. Joseph Newhouse (1970) and Martin Feldstein (1971) studied the implications of the maximization of quantity-quality subject to a budget constraint. Millard Long's model is one of quantity maximization subject to both a budget and a quality constraint. Paul Ginsburg assumed maximization of weighted output subject to a budget and an availability of capital constraint. Maw Lin Lee included types of physical capital in the hospital objective function. And Melvin Reder talked of hospitals trying to maximize "the weighted number of patients treated (per time period), the 'weights' being the professional prestige to the doctors attending them" (p. 480).

This last model is the only one to (even) hint at a nonpassive role for the physician in a model of hospital behavior.[2] In this paper we propose an alternative model in which the physician emerges as a traditional income maximizing economic agent who is "discovered" in a decision-making role within this not-for-profit enterprise. Our model is similar to the model of the firm customarily used by economists, in that it is based on the assumption of net income maximization. Only a somewhat unusual definition of net income is needed to enable us to apply in our short-run analysis many of the conclusions of the orthodox model of the firm. In the longer run, however, our model, while still based on net-income maximization, yields different predictions about the institution's response to changes in demand and supply parameters. Furthermore, it may be possible to generalize parts of our model to other private, nonprofit service firms such as universities and symphony or-

[2] Paul Feldstein and Carl Stevens have discussed the role of the physician in the hospital, but have not provided an explicit model.

chestras, which produce and sell services to individual consumers, many of whom are not poor.

Specifically, we assume that the group of attending physicians on the hospital's staff enjoys *de facto* control of the hospital at any point in time. Given this assumption, we develop a model in which the hospital operates in such a way as to maximize the net income per member of the physician staff. Results are obtained which are similar to those derived from models of producers' cooperatives in Yugoslavia and collective farms in the *USSR*. The physician plays a role analogous to that of the Yugoslav worker and the Russian peasant. Our results are also similar to those obtained from the "theory of clubs," developed by James Buchanan and others.

I. The Model

We simplify the problem initially by assuming that patients pay the full market price for care, and that the decision-making group in the hospital is able to impose its collective will on individual members. The implications of weakening these assumptions to allow for customary forms of health insurance and for imperfect cooperation among controlling individuals will be discussed in later sections.

The product produced in the hospital is hospitalization services. We shall assume that this output can be represented by a single variable Q.[3] To produce this output, physical capital (K), nonphysician labor (L), and physician or medical staff labor (M) are used. The production process can be summarized by the production function

$$Q = F(K, L, M) \tag{1}$$

In European countries in which physicians who treat patients in the hospital are employed by and paid by the hospital, this three-input production function is the obvious one.[4] But in the United States, the hospital patient is subject to two separate billings. The hospital charges him only for the use of capital and nonphysician labor. The physician presents a separate bill for the use of his "personal" physician's services. This dual billing system has led to a conceptually false dichotomy in much of the health economics literature. The physician and hospital are often viewed as independent economic entities selling services in functionally segmented health markets. This view appears to provide the rationale for the hospital-administrator-oriented, output-maximization theories of hospital behavior discussed earlier.

We propose an alternative view. It seems obvious that the patient's demand is primarily for the service produced by the physician and hospital acting in combination, not for the separate components, even though there probably is a separate demand for some attributes, such as amenities, or additional patient days for recuperating, that the hospital alone produces.

The critical assumption of our model is that the physician staff members enjoy *de facto* control of hospital operations and see to it that hospitalization services are produced in such a way as to maximize their net incomes. The appearance of physician control is not hard to establish. The staff physicians have direct control over the number and types of patients admitted and over the types of services

[3] Derivatives of two quite different surrogates for hospital output have been used most often by economists doing empirical research. One is based on the number of inpatient days and outpatient visits at the hospital while the other is concerned with the number of cases treated in the hospital. The "case treated" corresponds most closely with the measure of output implied by our model.

[4] This was the form used by M. Feldstein (1967) in in his study of hospitals in the United Kingdom.

they receive; they control output. The staff physicians can determine, within rather broad limits, what use of the hospital will be made in treating a patient; they control many of the production decisions. They have indirect control over many other aspects of the hospital's operation, such as capital investment and the level of nursing care, in the sense that no administrator can afford to incur the displeasure of the medical staff, interfere with medical staff prerogatives, or make decisions which will deter large numbers of physicians from remaining on the hospital's staff or using that hospital for their patients. The trustees, who have nominal control over the hospital's operation, usually look to the medical staff when making decisions on operations or capital investment.

We first assume that the physicians on the staff of a hospital at any point in time act in such a way as to maximize the sum of the money incomes of all staff members. Such an assumption implies a process of group decision making resulting in a kind of perfect cooperation not likely to be observed in practice. It also ignores nonmonetary components of a physician's income, such as leisure time and prestige, which are likely to be of some importance. Nevertheless, this model is useful as a bench mark from which to consider the effects of alternative assumptions.

We postulate an economic short-run period as one in which the number of physicians on the hospital staff, M, remains constant. Each physician is presumed to supply a constant, homogeneous amount of medical input.

The patient's demand is primarily for the service produced by the physician and hospital acting in combination, not for the separate components. This can be formalized by postulating a demand function for "hospitalization services" faced by the physician staff that takes the form

$$(2) \qquad Q = Q(P_T), \qquad \frac{\partial Q}{\partial P_T} < 0$$

where P_T is the combined price paid by the patient for the physician and hospital components.[5,6]

We also assume that the hospital component of P_T is set so as to allow the hospital to just break even, with no gain or loss.[7] That is, we assume that the hospital price P_h is set to produce the equality:

$$(3) \qquad P_hQ = wL + cK$$

where P_h is the unit price the hospital charges for use of nonphysician labor and capital, w is the wage rate for nonphysician labor, and c is the user cost of capital.[8]

[5] Some empirical justification of this assumption may be found in Donald Yett et al, where it was estimated that the elasticity of demand for *hospital* output with respect to *surgeons'* fees is 0.7.

[6] If the market for output is perfectly competitive, $|\partial Q/\partial P_T|$ will be infinite; otherwise, the individual hospital demand curve for output will have a negative slope.

[7] If the hospital received contributions, it may set a target loss equal to the contributions, but this will not alter our analysis. Moreover, after the fact the hospital may have a profit or loss, but this is assumed to result wholly from stochastic factors.

[8] The interpretation of the user cost of capital c is worth comment. When capital is provided through borrowed funds, the interpretation is clear; c is equal to $(r+d)P_K$, where r is the interest rate at which the funds were borrowed, d is the depreciation rate, and P_K is the price of capital goods. When unrestricted donations are used to pay for the marginal unit of capital, the user cost is $(r'+d)P_K$, where r' is the opportunity cost of using contributed funds for hospital physical capital, i.e., the rate which could have been earned on those funds if they had been invested elsewhere (say, in government bonds). When donations are made with the restriction that they be used for physical capital investment, they will affect the marginal user cost of capital only if the hospital receives so much in donations that it does not have to turn to any other source for funds for capital investment (unless, of course, the conditions for contribution of restricted funds specify a certain amount of the hospital's own funds as matching payments). If restricted donations fall short of the amount which, given the interest rate r, the hospital wishes to invest so that the hospital borrows, the relevant *marginal* user cost of capital must involve the interest and depreciation rates. Except for the case in which restricted donations are so large that the amount

The hospital is to be run so as to maximize the net incomes of the physicians on the staff at any point in time. If the number of physicians in the short-run analysis is taken as given at $\overline{M}$, the problem is to maximize $P_TQ - P_hQ$ (which is equal to $P_TQ - wL - cK$) subject to the production function (1), with the level of M set at $\overline{M}$, and the demand curve (2). This problem is obviously identical to that facing an orthodox profit-making firm with one input held constant. The marginal conditions for optimal employment of labor and capital are the same, namely, that marginal factor costs equal their respective marginal revenue or value products.[9]

It may be useful at this stage to contrast the model of the nonprofit hospital just developed with the orthodox model of the profit-maximizing firm. In the latter case, all labor inputs and capital services financed by debt are paid their competitive costs. Nondebt capital then obtains the residual income, which is usually assumed to consist of payment of the opportunity cost of that capital (normal profits) and economic profit. The only difference between this model and the physician-profit maximization model of the hospital is that in the latter it is the physician input, rather than the nondebt capital input, which obtains economic profits, the residual income. If a profit-maximizing firm submitted two bills for its services—one just covering the cost of labor and debt-financed capital, produced in a "nonprofit" firm, and the other from a separate legal institution covering the services of equity capital, the analogy would be complete.

II. Long-Run Individual Hospital Equilibrium

The number of physicians on the staff of any hospital obviously is not fixed, but is variable over time. What determines the size of the hospital's staff? The answer to this question depends critically on the assumption made about the hospital's staffing policy. We shall outline the results of three alternative policies—closed staff, open staff, and a policy in which new physicians can be hired by the hospital.

Closed staff

Many hospitals in the United States restrict staffing privileges: they do not permit any physician to join the hospital's staff just because he wishes to do so, even if he is licensed to practice medicine and surgery. The decision on whether or not to admit a new member to the staff (or whether to replace a member who has left) is made by the existing members of the hospital's staff of physicians. If we

of capital that is bought with them exceeds the amount which would be indicated by the marginal conditions, donations, whether unrestricted or restricted, are really equivalent to lump sum subsidies. Only if the hospital's price and output policies affect contributions (and within wide margins, they do not seem to) should contributions be treated as other than lump sum grants. In a world of uncertainty, however, the total of donations past and present may affect a lender's willingness to lend, since they provide collateral. Even in this case, current donations are likely to be important only if they are large relative to total nonborrowed capital.

[9] The model implies cost minimization in the sense that, given the physician input, quantities of labor and capital are chosen which, given their marginal supply prices, minimize costs. Cost minimization is also a characteristics of output-maximization models. However, normative conclusions that have been derived from empirical cost function studies regarding socially optimal scale of hospital facilities are considerably weakened when it is realized that there is no reason to suppose that, in comparisons across hospitals or over time, the physician input actually is constant, or even variable in a random way. The physician input has been left out of cost and production function studies of *U.S.* hospitals. Unless the physician input is specified or is known to be a constant ratio to K and L, there is no way of knowing the true social costs of all the inputs associated with any scale of output, and hence no way of determining the cost-minimizing scale. Observed decreasing hospital costs, for instance, may only represent a systematic increase in physician input with size. Furthermore, when we allow imperfect cooperation of the physician staff in our model in a later section, we will find that minimization of even nonphysician costs in the technical sense by the hospital is a very unlikely conclusion.

assume that once a physician is admitted to the staff, he has privileges identical to those of the existing members, the appropriate maximand for the hospital appears to be the maximization of net income per physician, Y_M. Physicians will be willing to add members to the staff as long as it causes each member's net income to rise.

This implies that the objective function to be maximized is

$$(4) \qquad Y_M = (P_T Q - cK - wL)/M$$

subject to the production function (1) and the demand curve (2). The necessary first-order conditions for an extremum become

$$(5a) \qquad w = P_T \frac{\partial Q}{\partial L} + \frac{\partial P_T}{\partial Q} \frac{\partial Q}{\partial L} Q$$

$$(5b) \qquad c = P_T \frac{\partial Q}{\partial K} + \frac{\partial P_T}{\partial Q} \frac{\partial Q}{\partial K} Q$$

$$(5c) \quad Y_M = P_T \frac{\partial Q}{\partial M} + \frac{\partial P_T}{\partial Q} \frac{\partial Q}{\partial M} Q$$

In long- or short-run equilibrium, the physician-hospital conglomerate firm that we have postulated will equate the marginal supply price of all nonphysician inputs to their respective marginal revenue or value products. However, in our model, physicians all share equally in the residual income of this health enterprise, the shares depending on their assumed equal shares of a total output. Condition (5c) states that physician staff size is determined in long-run equilibrium by equating the marginal revenue product of physicians to the net average revenue product of the physician staff. This makes intuitive sense. The hospital "pays" for new physicians by allowing them a proportionate share of total output and, hence, of net revenues. Staff physicians will want to welcome warmly a new member as long as his contribution to total revenues of all staff physicians is greater than the average current income per physician which he receives.

Of course, condition (5c) cannot be satisfied unless there are physicians willing to work at the hospital for the earnings available. That is, the equilibrium value of Y_M must be at least as large as the income stream available to a physician in his next best opportunity. There will be a supply curve of physicians to any hospital. The shape of this curve will depend in part on the income a physician could get in other hospitals, and his valuation of other uses of his time, both as leisure and as office practice.

Figure 1 depicts the long-run equilibrium position of a hospital operating in an urban, physician-intensive environment. The physician supply curve, SS, may therefore be assumed to be approximately infinitely elastic, and we also assume that it is at a low level relative to income possibilities in this particular hospital. Within the hospital, capital and nonphysician labor take on short-run optimal values as physician staff size, M, varies along the horizontal axis. ABC thus represents the maximum attainable income per physician for each specific value of M. Returns to scale and elastic demand lead initially to the upward sloping segment of ABC, but eventually decreasing returns and diminishing marginal revenue cause the curve to turn down. The maximum maximorum, Y_M^*, of this set of short-run maximums is reached at the intersection of the marginal revenue product and net average revenue product curve, when physician staff size reaches its long-run equilibrium value of M^*.

This model is very similar to those developed by Benjamin Ward (1958, 1970), Evsey Domar, Walter Oi and Elizabeth Clayton, Jaroslav Vanek, and others who explain the economic behavior of the Soviet collective farm or the Yugoslav producers' cooperative. The physician

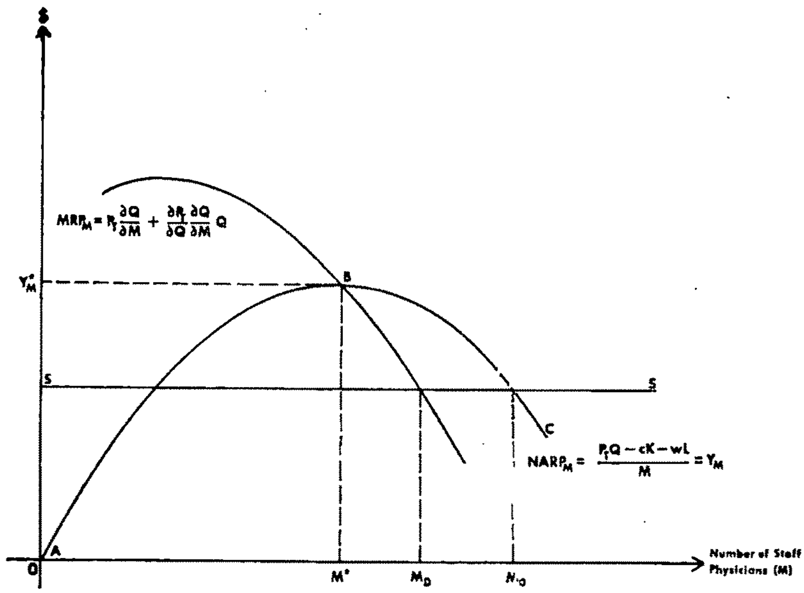

FIGURE 1

plays a role analogous to that of the Russian peasant and the Yugoslav worker. Institutionally, the arrangements differ because the physician receives his "share" of the enterprise's income directly from the sale of his output, whereas the worker on a collective receives it from a common pool. But this is because, in the case of the hospital, output can usually be directly assigned to particular staff members.

Our model of the hospital shares certain of the seemingly paradoxical conclusions of these cooperative-collective models. Supply response to changes in product and factor market conditions can be in perverse directions. An upward shift in the demand curve for hospital output could result[10] in a new equilibrium with higher price levels, *lower* output, and *fewer* physician staff members to share the greater total net revenues of the physician-hospital conglomerate enterprise. "Members have an incentive to contract membership to hoard the spoils" of a demand increase (see Oi and Clayton, p. 43). An increase in a factor price may lead to an expansion of operations to help spread the misery around among a larger group of individuals. On the other hand, a lump sum subsidy, such as a philanthropic contribution, will decrease output and staff size. "Even when the co-op moves in the same direction as a capitalist firm, its response is usually more sluggish. For market stability, the picture is not particularly reassuring" (see Domar, p. 739).

The reason for this result can be sketched out briefly:[11] Suppose a hospital faces a given price for output, and price increases by some amount. This will produce a proportionate increase in the marginal revenue product of physicians, assuming that K and L are held constant, but the income per physician (Y_M) will increase more than proportionately. The

[10] Unambiguous results concerning the direction of supply response cannot be determined unless specific restrictions are placed on the nature of the demand shift and the form of the production function.

[11] For a more extensive development, see the references cited in the preceding paragraph.

maximum average income would be attained at a smaller value of M.

The values of K and L will not, of course, remain constant. They will increase in response to increases in their marginal products. But M^* will still decline unless increases in K and L increase the marginal revenue product of physicians and do so by a large enough amount to offset the increase in average income. This need not happen; Q and M^* may decrease, or not increase much, whereas in a profit-seeking firm the use of an input and the amount of output would almost certainly increase with a rise in the price of output.

Discriminatory Sharing or Hiring Model

To consider the consequences of altering the "equal sharing" assumption, we suppose that the hospital depicted in Figure 1 is allowed to hire physicians at the supply price, OS. The hospital will then organize production in the same way as would a profit-maximizing firm. The physician input will be increased until the marginal revenue product and the marginal supply price of physicians' services are equal to each other. Staff physicians will be able to capture, in their own incomes, the excess of the marginal products of the infra-marginal hired physicians over their supply price. Equilibrium will be at M_D. But note that there is explicit discrimination in returns to homogeneous labor in this situation; the ability to sustain a stable equilibrium under these circumstances is highly suspect. As Pauly has shown, a system of clubs in which some identical persons receive less than others is not likely to be stable. It may well be that the internship-residency programs so prevalent in the United States may be an institutionalized method of getting around the inherent instability in the discriminatory hiring model by creating artificial, functionally viable distinctions among homogeneous physicians.[12] Determination of the ratio of "partner" physicians to "hired" physicians is likely to be arbitrary. The economic well-being of those physicians left with full staff privileges varies inversely with this ratio.

Open Staff Model

Alternatively, we can retain the "equal shares" assumption, and examine the economic behavior of hospitals that do not restrict entry to their physician staff. Any licensed physician who chooses to do so may become a "full partner" in the firm. Equilibrium at M_o in Figure 1 is characterized by equality of average income per member of the physician staff and the marginal supply price of physicians services.

Of course, for a hospital in a rural area with few physicians, or in an area where many physicians have attractive alternatives to membership on that hospital's staff, the situation might be somewhat different. Faced with a sharply rising supply curve for physicians' services, $S'S'$ in Figure 2, the physician staff will be in equilibrium at M_{oo}. The hospital might as well call its policy "open staffing," since it would be willing to add new members in order to move up the rising part of the net average product curve and increase income per staff member. Such a "frustrated closed staff" hospital only needs to adopt a closed staff policy when the number of staff members reaches M^*.

Note that the discriminatory-hiring and open-staff hospitals, either the "true"

[12] Interns and residents serving in *U.S.* hospitals currently comprise about 15 percent of all MD's and, of course, provide a considerably higher percentage of hospital based physicians' services. In several of the cost function studies, there have been attempts to estimate the effect these physician trainees have on hospital costs and revenues. Our model would suggest that it might prove more fruitful to analyze the ways in which trainees can increase the incomes of those physicians with regular staff privileges.

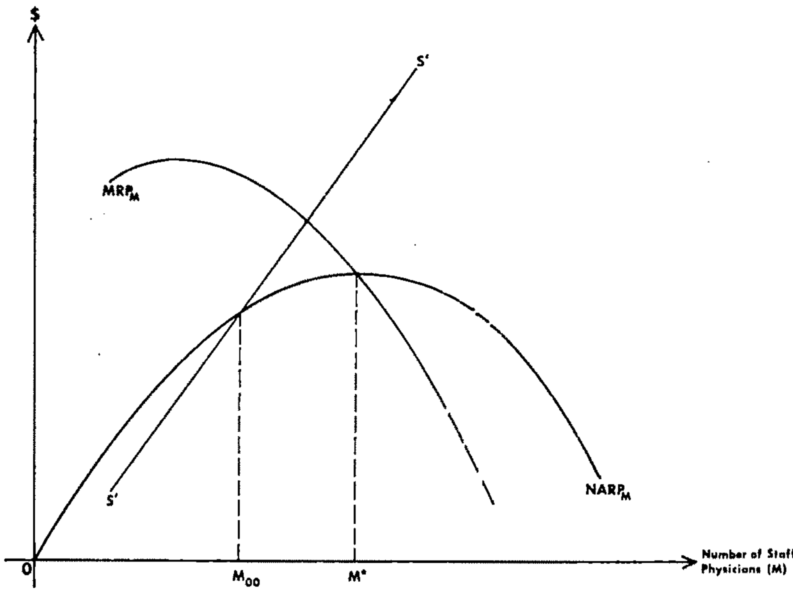

FIGURE 2

open-staff hospital or the frustrated closed-staff one, do not exhibit the potentially perverse supply responses that were uncovered in the closed staff model. Increases in demand will lead to increases in physician staff and output.

III. Long-Run Industry Equilibrium

The closed-staff hospital in the long run tries to adjust its physician staff size to achieve maximum income per physician. But if physicians in a hospital achieve incomes below those of other identical physicians on the staffs of other hospitals in that area or in other areas, the low-income physicians may wish to join the staffs of high physician-income hospitals. If they are prevented from joining the staffs of existing hospitals, as would occur if those hospitals were large enough so that average income was maximized, it will be worthwhile for M^* of those rejected physicians to join a new hospital, a duplicate in size of the old one. Indeed, the formation of new hospitals will continue as long as higher incomes can be earned, bidding up the supply price of physicians and bidding down the price of final output (and hence the curve of average income) until a position of long-run equilibrium is attained at which average income, marginal income, and marginal supply price are equal to each other and equal across hospitals. In the open-staff model, long-run equilibrium is also reached by the formation of new hospitals, but here the new hospitals draw off excess members from existing hospitals, raising average incomes since average size shrinks. This process will continue until formation of a new hospital does not raise average income. Finally, in the discriminatory-hiring model, physicians who are paid less than staff physicians (i.e., hired) will find it advantageous to try to join a hospital of their own in which they are all staff members and receive incomes equal to those of physicians in existing hospitals.

Thus these models have identical long-run industry equilibria (when the number of firms is variable), but the closed-staff model has a radically different long-run firm equilibrium, and may move in a perverse direction from that of the discriminatory-hiring firm. The open-staff model, on

the other hand, responds in the same way as would the discriminatory-hiring (or profit maximizing) hospital, but is likely to have a quantitatively different response. Although the final industry outcomes under these institutional arrangements are the same, the adjustment process by which that outcome is reached is very different in each case.

IV. Imperfect Cooperation on the Hospital Staff

In this section we wish to relax the assumption of perfect cooperation by the hospital's staff of physicians. The *individual* physician may in fact have direct control over the process of producing output. He is able to order use of nursing and other inputs for his patients, in his character of professional expert. At best, "the hospital" can determine only a stock of inputs; the physician controls the flow of services from them. This is in contrast to a producers' cooperative (or even a nonprofit university) in which, presumably, a central management is somewhat more able to prevent individualistic behavior. Moreover, each physician's income from the hospital-connected services depends entirely on his own output, in contrast to the producers' cooperative model in which an individual worker's income partly depends on his own output but also depends on his share of total profits or surplus income. The physician shares group income insofar as he shares group output.

We assume, as before, that the hospital price is set at a level which permits the hospital to break even. It is now easier to see why this assumption is itself a consequence of the physician profit-maximization hypothesis. Other things being equal, hospital profits mean higher hospital prices, which reduce physician incomes. To be sure, hospital profits could be used for capital investment which may enhance future physician incomes, but 1) physicians may not want to invest in the hospital—and 2), as Eirik Furubotn and Svetozar Pejovich have noted, the fact that property rights are not vested in investment from profits makes it even less desirable than owned investment.

Since prices for services are not (yet) set at marginal cost,[13] and since the physician does have the power to direct the application of labor and capital services in producing his output, noncooperative behavior can occur. Suppose the hospital follows the policy of charging an all-inclusive daily rate. Suppose ordering the use of more labor in the production of some output will permit the physician to charge more for that unit of output, because the "quality" of the output is enhanced. If the application of more nonphysician labor raises the price P_T^i that can be charged by the ith physician but if the same price P_H is charged for all units of hospital output, regardless of whether or not extra labor is ordered, the physician will want to use labor for his Q_i patients up to the point at which the following equality is satisfied:

$$\frac{\partial P_T^i}{\partial L} Q_i = \frac{Q_i}{Q} w \tag{6}$$

That is, the individual physician only considers a fraction Q_i/Q of the cost of the labor he orders to be employed, whereas group profit maximization would require him to take account of the costs his action imposes on other physicians' patients. Consequently, imperfect cooperation leads

[13] In fact, it does not appear that hospitals do price at marginal cost. They have moved away from the use of an all-inclusive daily rate, the same for all patients, toward itemized bills, but they are still far from charging marginal cost as a price. And in theory, it is unlikely that prices could be set equal to marginal cost. Unless marginal cost just equals average cost, marginal cost pricing by the hospital of its services would violate the no-profit, no-loss constraint assumed above. Moreover, the use of different prices for different qualities of outputs involves transactions and information costs, which may be substantial.

to the use of too much labor relative to the amount that would be used if group incomes were maximized with perfect cooperation.

How great these departures from perfectly cooperative usage will be depends upon how well the staff as a group can control the actions of its individual members. It seems reasonable to suppose that the magnitude of the departure from cooperative behavior should get larger as the size of the staff gets larger.[14] There are at least three reasons for making this assumption. 1) When the staff size is small, each physician bears a larger share of the cost of his own actions. 2) When the staff size is small, departures from cooperative behavior on the parts of others are more noticeable to any single member. 3) When the staff size is small, mutually agreeable group decisions are more likely to be arrived at, since the cost of decision making is less.

In terms of the geometric analysis, introduction of imperfect cooperation in this way shifts the curve of net revenue per member down and to the left. The conclusion is obvious; lack of perfect cooperation makes the (second best) optimal size of the staff and hospital smaller than it would otherwise be.

V. The Effect of Insurance

To this point we have assumed that patients confronted the full market price for care. Insurance coverage of medical costs may weaken the applicability of this assumption. The hospital is typically paid on the basis of costs incurred. If there are no copayments or deductibles at all, this arrangement effectively eliminates market control over the hospital component of the price of hospitalization, since higher hospital costs and prices have no effect on the cost actually paid by the patient (except through the premium, which only matters if the premium rises so high that the person drops coverage). Moreover, the allocation of costs within the hospital to insured patients, especially Blue Cross members, is often done on average cost basis. The only restraint on the physician's prescribing the use of hospital capital and labor for his fully insured patient is the upward pressure his behavior would exert on the prices paid by his noninsured patients. Conversely, under average cost allocation some of the market discipline is lost for the noninsured by the transfer of some costs to the insured.

If every patient had full coverage cost-based hospital insurance, there would be no constraint on the amount of capital and labor that physicians combine with their services. Capital and labor would therefore be employed up to the point at which the marginal contribution of each to the physician's revenue was zero. This produces "Cadillac-quality" medicine. The only constraint on the use of these inputs would be offered by the upper limit on the number of things a hospital can do for a patient which might have some justification. Over time, technological change might be expected to relax even this constraint.

When insurance covers part of each patients' hospital bill, the factor prices of hospital inputs K and L are effectively reduced as far as the group of physicians is concerned. One would expect an increase in the usage of hospital inputs relative to physician inputs for producing a given output. Hospital unit costs would rise. Thus our model provides an explanation of the positive relationship between hospital insurance coverage and hospital unit prices and costs found by M. Feldstein (1971). In addition, our model yields the important result that, *ceteris paribus*, increased

[14] A similar analysis of the effect of size is provided by Mancur Olson. Other applications to medical care can be found in the work of Newhouse (1972) and Mather Lindsay.

hospitalization insurance should increase physician prices and physician incomes.

VI. Toward a Theory of the Not-For-Profit Enterprise

To this point we have taken the not-for-profit nature of the typical American hospital as given. In this section we offer an explanation of why this organizational form has arisen.

There are two ways in which the hospital might operate if it were on a profit-maximizing basis. It might combine the services of nonphysician labor and physical capital, and sell them to or through the physician, who combines them with his own input to produce the output of hospitalization services. Alternatively, the hospital might perform the job of combination itself, hiring the physician input and selling the final output. In either case the direct control over the use of nonphysician labor and capital would not be held by the physician. In the first case, he would have to use the market for control, which is not always efficient in the sense of minimizing all costs, including transactions costs, as direct control. In the second case, he himself would be under the direction of the supplier of equity capital. It is surely possible that there are some products which are not produced efficiently when a representative of the owners of equity capital directs their production, or when the market is used to organize the production process instead of the use of direct controls within a single organization. The most efficient method might be for the supplier of an important component of the labor input to direct the production process.

This would tend to happen when human capital is important in the production of some output and when the flow of services of that human capital cannot well be directed from outside, but is controlled by the person in whom the capital is embodied. As Armen Alchian and Harold Demsetz have noted, the wage system tends to break down when marginal products cannot be monitored closely. This may be a reasonable conjecture in the case of the production of hospital services. Many of the decisions the physician has to make are decisions which cannot be supervised directly, and which have contingent outcomes. There probably needs to be some incentives for the physician. Financial interest in the outcome of his actions is one such incentive, and that incentive is at its greatest when the physician bears the full residual income, when the consequences of his actions are not spread over suppliers of physical capital.[15]

The production process requires some physical capital. In a labor-managed firm in which most of the assets of labor are embodied in nontransferable human capital, not all of the physical capital can be borrowed, since collateral cannot be provided. Another necessary condition therefore for the emergence of the not-for-profit form would seem to be the willingness of individuals to contribute for its equity capital. In principle, contributions could either be voluntary or provided through government. Where voluntary contributions are sufficient, government contributions would not be expected to emerge. On the other hand, voluntary contributions may arise in precisely those cases in which the government fails to act. They may also arise in cases in which the government through tax deductibility

[15] To see this, think of each physician as a "firm." The socially most efficient institutional arrangement is the one which maximizes the net present value of this firm. The present value is a contingency, depending on the state of nature (for example, what's really wrong with his patients, whether an epidemic occurs, etc.) and the amount of effort that the physician makes. The amount of effort, in turn, depends upon the share of profits the physician receives. The appropriate share for the physician, even given the greater risk he bears, may be approximately equal to one.

subsidizes private contributions. The source of contributions, whether unsubsidized voluntary, subsidized voluntary, or governmental, is not critical to the argument, except to the extent that one form (for example, government) implies more external control over physicians' actions than another.

These contributions could be motivated by a desire on the part of contributors to make output available to themselves or to those whom they would like to see consume it. That is, the motivation could either be based on the potential receipt of private benefits or of external benefits. Contributions are a logical way for potential purchasers of the outputs of labor-managed firms to make possible production of the output, which they or those about whom they are concerned will use. If there are barriers to entry by profit-seeking firms (as there are in higher education and, to some extent, in the hospital industry as well), potential consumers may be willing to contribute if that is the only way that output, which yields them consumers' surplus, can be made available. It is not surprising that private not-for-profit firms which sell output—hospitals, universities, symphony orchestras—tend to provide output which is used *not* by the poor, but partly by the contributors themselves.[16]

VII. Conclusion

The main thrust of the model we have suggested here, and the one which differentiates it from models of the not-for-profit hospital that have been suggested by others, is the use of the maximization of physicians' income as the characteristic function. The potential absence of perfect cooperation distinguishes it from similar models of producers' cooperatives. In a methodological sense, our model seems to be more attractive than those which simply assume that the not-for-profit organization maximizes a variable such as "quantity of output," because it explains what the organization does in terms of the economic motivation of those who control it.

More importantly, it appears to provide an appealing explanation of some peculiar characteristics of not-for-profit hospitals. The supposed quality consciousness of such hospitals, for example, is easily explained; "quality" is a synonym for application of nonphysician labor and capital in physician-income-enhancing ways, and noncooperative behavior could easily lead to "too high" quality. "Duplication of facilities" probably owes its existence to closed staffing and lack of perfect cooperation. Other aspects of hospital behavior could also be explained by considering their effect on physicians' income; the pattern of investment, for example, might be best explained by changes in the ability of capital to enhance physicians' incomes. The inelastic supply response of hospitals to Medicare and Medicaid is also consistent with our model.

Even the average size of hospitals, which seems, by most accounts, to be below the optimal or cost-minimizing level, can easily be explained. In the first place, empirically observed cost curves may be misleading, if we add the physician input. But more importantly, in a period of rising prices our model shows that hospitals will tend to be small, and for two reasons. First, smallness tends to permit maximization of net income per physician. Second, smallness is necessary to permit coordination of the medical staff.

[16] This last point is an important consideration. It is sometimes alleged that these firms have attained a nonprofit status so that they may better provide services to the poor. However, the recent experience in this country is for the poor to receive health services from government operated hospitals, to receive education in government operated institutions, and not to partake at all of the output of symphony orchestras, theatre groups, or private universities.

A narrower range of possible observations is consistent with our model than with the general utility-maximization model. Appropriate choice of the variables to enter the utility function can make almost any observed behavior consistent with utility maximization. In particular, the definition of quality is not clear. Our model specifies the variable in the objective function. In principle it will also predict quantitative as well as qualitative responses, in the sense that physician income can be measured while utility cannot. Unfortunately, at present hospital-specific data on physicians' incomes or prices do not exist which would permit us to provide a conclusive test of the model. Nevertheless, we hope that more data can be made available to test this model.

Capital, Distribution, and the Aggregate Production Function

By DONALD J. HARRIS*

Recent results in capital theory concerning the reswitching of techniques of production have shaken the foundations of a neoclassical parable according to which the total quantity of output per man is supposed to be a function of the total quantity of capital per man—the Surrogate Production Function—which can be used to "predict all behavior" in the sense of the wage and profit rates that would prevail in different long-run equilibria or steady states.[1] The source of the difficulty, it would appear, lies in the fact that the neoclassical parable attempts, as it were, to kill two birds with one stone, namely 1) to provide a general representation (or "surrogate") of realistic technologies involving production with heterogeneous commodities, and 2) to link the determination of the distribution of income directly to the technology itself and to the relative size of "factor endowments." It turns out that, in general, not only are realistic technologies not representable by such a function but also there is no one-to-one correspondence between techniques of production, the quantity of capital per man, and the distribution of income. These results have thus opened the way to a critique of the marginal-productivity theory of distribution in terms of its logical foundations (see P Garegnani). At the same time, they enable a return to certain classical conceptions concerning determination of income distribution in a capitalist economy (see A. Bhaduri (1969), Joan Robinson (1971), ch. 3).

The central proposition which is called into question by the recent results is that concerning the existence of a monotone-decreasing relation between the quantity of aggregate capital per man (the capital-labor ratio) and the rate of profit.[2] It has been shown that, in general, there exists no such relation: the relation between capital per man and the profit rate may be of any form. However, discussions concerning this relation have been unclear as to the exact features which account for its shape. Reswitching of techniques no doubt enters into it. But, even in the absence of reswitching of techniques, there may not be a one-to-one correspondence

* Associate professor of economics, University of Wisconsin, Madison. I have benefitted from discussions with Joan Robinson, Krishna Bharadwaj, Luigi Pasinetti, and John Eatwell and from correspondence with Luigi Spaventa.

[1] The concept of the Surrogate Production Function is due to Paul Samuelson (1962). The reswitching results are discussed in the 'Symposium on Paradoxes in Capital Theory." For a review of the issues and the controversy surrounding them, see G. C. Harcourt, Robinson (1970).

[2] This relation is derived from the production function through the requirement that the equilibrium rate of profit is equal to the marginal product of capital which is in turn a unique inverse function of the capital-labor ratio. On this, see the Appendix. Recognizing that there are "major troubles" with the neoclassical production function, J. R. Hicks, ch. 24, has proposed as an alternative a "sophisticated production function." He claims for this alternative that: "We can draw out a curve that expresses values of [capital per man] that are consistent with equilibrium for different [rates of profit]; it is highly probable that it will be a downward-sloping curve" (p. 298). The arguments considered here apply also to this conception. Another basic proposition of the neoclassical parable which is called into question by the recent results concerns the relation between consumption per man and the profit (interest) rate. Consideration of this is omitted here but the argument is easily extended to that relation.

between capital per man and the rate of profit.[3] Certain other features are relevant, some of which have customarily been discussed in terms of the category of "Wicksell Effects" (see Bhaduri (1966), Harcourt, pp. 397–400).

For the purpose of isolating these features, this paper seeks to identify more closely the various elements underlying the relationship between value of capital and rate of profit. The setting of the problem is in the comparison of different steady states which may be stationary or growing. There is no implication here of a *process of change* from one equilibrium to another. Different equilibria are to be regarded as if they were different planets with no connection between them. A clear distinction is maintained throughout between physical or technological relations and price relations. It is then possible to separate the differences involved as between one equilibrium and another into three categories: a *price effect*, a *composition effect*, and a *substitution effect*.[4] From this analysis, the proposition that the rate of profit is equal to the "marginal product of capital" also emerges in a new light.

I. Production, Prices, and Growth

It is helpful to carry out the analysis in the context of the familiar two-sector model of capital and consumption goods production.[5] Technology is specified in terms of a book of blueprints containing a list of the available techniques which may be finite or infinite in number. For any given technique, say α, the equilibrium price equations in terms of the consumption good as numeraire are:

$$(1)\quad p = b_1 w + v_1 p(\delta + r) \text{ (capital good)}$$

$$(2)\quad 1 = b_2 w + v_2 p(\delta + r) \text{ (consumption good)}$$

where

p = price of capital good
w = real wage rate
r = rate of profit
δ = rate of depreciation of capital good
b_1, b_2 = labor coefficients
v_1, v_2 = capital coefficients

$$\mu = \frac{v_2 b_1}{v_1 b_2} = \text{ratio of capital-labor coefficients.}$$

These yield equations for the *wage-profit curve* of the individual technique and the price of the capital-good which are, respectively,

$$(3)\qquad w = \frac{v_1(r^* - r)}{b_2 \xi(r)}$$

$$\xi(r) = \mu - v_1(\mu - 1)(r^* - r) > 0$$

$$0 \leqq w \leqq w^* = \frac{1 - v_1\delta}{b_2[1 + (\mu - 1)v_1\delta]}$$

$$0 \leqq r \leqq r^* = \frac{1}{v_1} - \delta$$

$$\frac{dw}{dr} < 0, \quad \frac{d^2w}{dr^2} \gtreqless 0 \quad \text{if} \quad \mu \gtreqless 1$$

$$(4)\quad p = \frac{b_1}{b_2 \xi(r)}; \quad \frac{dp}{dr} \gtreqless 0 \quad \text{if} \quad \mu \lesseqgtr 1$$

Similar conditions hold for techniques β, γ, . . . ω, allowing for differences in their respective production coefficients

There are as many wage-profit curves as there are alternative techniques in a given book of blueprints. Given any arbitrary

[3] An example of this was given by Pasinetti in his contribution to the "Symposium," p. 516. See also Spaventa (1968, p. 33).

[4] For a similar usage of the terminology of price and composition effects, see Spaventa (1968). A slightly different concept of "substitution-composition effects" is developed by Murray Brown.

[5] This model has the advantage that it is the simplest which captures a characteristic feature of realistic technologies, that is, production of heterogeneous commodities by means of commodities and labor. Its main limitation is that it does not allow for the existence of joint production in the use of fixed capital and for different time-patterns of production. Comparative equilibrium analysis in the context of this model has been treated by Hicks, Spaventa (1968, 1970), Garegnani, but with a rather different emphasis.

wage rate (profit rate), producers choose that technique which yields the highest profit rate (wage rate) or the wage-profit curve furthest out. The wage-profit curves corresponding to those techniques which are most profitable at some rate of profit generate an outer envelope or *wage-profit frontier*, curves that are dominated at every profit rate being discarded. With a finite number of discrete techniques, the frontier is made up of segments of the contributing curves and therefore has corners. Each corner corresponds to a *switch-point* between two intersecting techniques. With an infinite number of techniques the frontier is a smooth curve tangent at each point to one wage-profit curve. There may be *reswitching* of techniques such that a single curve contributes more than one segment or point to the frontier. In general, the frontier is negatively sloped and may have any curvature depending on the structure of the underlying technology. Because of the possibility of reswitching of techniques among those represented on the frontier, it is not possible in general to order techniques uniquely by the rate of profit.[6]

Add now the relations governing the levels of output (X_1, X_2), employment of labor (L), the stock of the capital good (M), the warranted growth-rate (g), and saving behavior. Saving behavior is represented by constant saving proportions s_r and s_w, respectively, for profits and wages, where $0 \leqq s_w < s_r \leqq 1$. As an alternative specification we consider the case of $s_w = s_r = s$. Accordingly, we have, for a given technique,

$$M = v_1 X_1 + v_2 X_2 \tag{5}$$

$$L = b_1 X + b_2 X_2 \tag{6}$$

$$X_1 = (g + \delta) M \tag{7}$$

$$pgM = s_r r p M + s_w w L \tag{8}$$

The model remains open with respect to one of the variables. To close it requires additional information which could be supplied by any of a number of possible theories. Without going into this, we focus instead on the characteristics of possible growth equilibria and on comparisons of such equilibria. Analysis of these properties provides us with the relations with which *any* relevant theory must be consistent.[7] As a basis for this analysis we obtain from the above system the following equilibrium relations:

$$c = \frac{X_2}{L} = \frac{v_1(g^* - g)}{b_2[\mu - v_1(\mu - 1)(g^* - g)]} \tag{9}$$

$$\frac{M}{L} = \frac{v_2}{b_2[\mu - v_1(\mu - 1)(g^* - g)]} \tag{10}$$

$$k = p\,\frac{M}{L} = \frac{\mu v_1 / b_2}{\xi(r)[\mu - v_1(\mu - 1)(g^* - g)]} \tag{11}$$

$$g = \frac{(s_r - s_w)\mu r + s_w r^* \xi(r)}{(1 - s_w)\mu + s_w \xi(r)} \tag{12}$$

[6] All of this is by now familiar, but bears repeating for the reason that it is basic to what follows. It may be noted also that everything said in this paragraph could as well be said about any technology in which commodities are produced by commodities and labor (compare Sraffa). The exception is that, with joint production (Sraffa) and with different time patterns of production (D. M. Nuti), the frontier may have both negative and positive slope. Otherwise, the simplifications introduced here are merely a matter of convenience. The wage-profit frontier is sometimes called a "Factor-Price Frontier" (see Samuelson (1962)). The present terminology is preferable because it does not presume a conception of profit as the price or reward of a factor of production. It is precisely this conception which is called into question by the results discussed here.

[7] This analysis is meaningful so long as the missing equation determines one of the variables in terms of exogenous parameters. A common formulation which fulfills this condition is the requirement that the system be on a steady-state path where the warranted growth rate is equal to the exogenous growth rate of labor. But there are others which would do just as well, for instance the Ricardian assumption of a wage rate equal to "subsistence," the Marxian assumption of a given rate of exploitation or Robinson's assumption of a rate of accumulation determined by "animal spirits."

where

$$0 \leqq g \leqq g^* = \frac{1}{v_1} - \delta$$

The accounting identities for net output per man (y) are

$$(13) \qquad y = w + rk = c + gk$$

II. Comparative Equilibrium Analysis: One Technique

In comparing different equilibria, special interest attaches to the relation between the rate of profit (r) and the value of capital per man (k). Assume, for simplicity, that there is only one technique which remains the same at every profit rate in the feasible range.

For the relation between k and r we have, by differentiation of (11),

$$(14) \qquad \frac{dk}{dr} = \frac{M}{L}\frac{dp}{dr} + p\frac{d(M/L)}{dg}\frac{dg}{dr}$$

It can be seen that there are two distinguishable components of the difference in k between different equilibria. The first is simply a difference in the price of the capital good associated with the difference in the profit rate. Call this a *price effect.* It is positive when the capital-labor coefficient is greater in the capital good sector and negative in the opposite case. When the capital-labor coefficient is the same in both sectors, the price effect is zero.[8] In this case, the classical labor-theory of value holds in its simplest form: price corresponds to labor value.[9]

[8] The reason for all this seems obvious when it is realized that there are two elements in cost: the wage rate and the profit rate, which vary in opposite directions. With a higher rate of profit (lower wage rate) costs rise more (fall less) in the sector which uses a higher proportion of the capital-good input to labor input. The relative price rises to reflect the difference in relative costs. If both sectors have equal capital-labor coefficients, the rise in one element of relative costs just offsets the fall in the other and consequently the relative price is unaffected.

[9] Setting $\mu = 1$ in (4) leads to $p = b_1/b_2$.

TABLE 1—COMPARISON OF EQUILIBRIA: SIGN OF dx/dr

x	$0<s_w<s_r$	$0=s_w<s_r$	$s_w=s_r=s$
$\mu>1$			
p	−	−	−
g	+	+	+
M/L	−	−	−
k	−	−	−
$\mu<1$			
p	+	+	+
g	?	+	−
M/L	?	+	−
k	?	+	?

The second component involves a more complex set of relations. With given saving proportions, when the profit rate is different the growth rate is likely to be different. This follows from the growth-profit relation (12) which represents the equilibrium condition for saving and investment. In addition, when the two commodities are produced by different methods ($\mu \neq 1$), a difference in the growth rate calls for a different stock of the capital good to produce the different composition of output which the difference in the growth rate entails (see equation (10)). Call this set of relations a *composition effect.*

The overall difference in the value of capital per man is the outcome of both the price and composition effects. The sign can be determined from the equations of the system.[10] These are shown in Table 1 for various cases. A question mark in-

[10] For the composition effect we have, from equations (10) and (12):

$$\frac{d(M/L)}{dg} = \frac{-v_2v_1(\mu-1)}{b_2[\mu - v_1(\mu-1)(g^*-g)]^2} \gtreqless 0 \text{ if } \mu \lesseqgtr 1,$$

$$\frac{dg}{dr} = \frac{\mu[(s_r-s_w)\mu + s_w(1-s_r)(\mu-1)v_1r^*]}{[(1-s_w)\mu + s_w\xi(r)]^2}$$

$$\gtreqless 0 \text{ if } \mu \gtreqless \mu^*$$

where

$$\mu^* = \frac{s_w(s_r-1)v_1r^*}{s_w(s_r-1)v_1r^* - (s_r-s_w)} < 1$$

dicates that the sign is ambiguous. This is because the price and composition effects are of opposite sign (when $\mu<1$, $s_w=s_r=s$) or because the composition effect itself is ambiguous (when $\mu<1$, $0<s_w<s_r$).

III. Many Techniques: The Discrete Case

When there is a finite number of techniques, the analysis in the previous section holds for each technique within the range of profit rates corresponding to the segment of its wage-profit curve included in the frontier. The additional feature which now concerns us relates to the comparison of equilibrium positions between which the technique of production is different.

We may call the difference in technique associated with a difference in the profit rate between two equilibria a *substitution effect*. The presence of the substitution effect means that the composition and price effects are no longer as sharply distinguishable as in the single-technique case. This is because the capital good may be different when the technique of production is different.[11] No quantitative expression in technical units of the capital good can then be given to the difference in the physical stock of each capital good associated with different equilibria. Neither can any meaningful comparison be made of the price of each capital good when they are different goods.[12] Instead, comparison has to be made of the value of capital expressed in terms of the numeraire commodity common to the different techniques.[13] This difference in value incorporates all three effects.

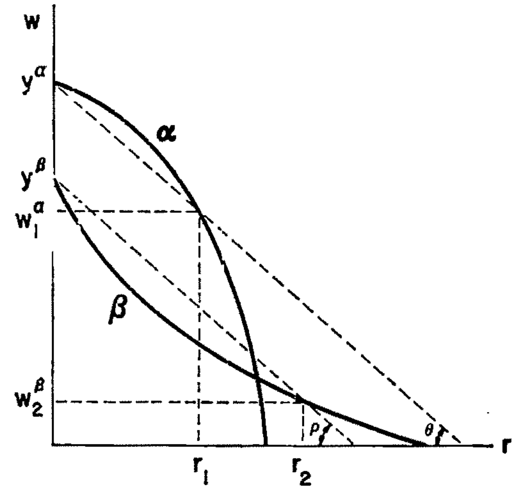

FIGURE 1

In comparing the various equilibria that are possible within the given conditions of technology and saving behavior, the same technique might be found in two different ranges of the profit rate. This reflects the existence of reswitching. The values of capital and net output per man for that technique in one range of the profit rate may be uniformly higher or lower than in the other range. These values may even be the same.[14] The result depends on the particular pattern of price and composition effects for that technique. There is, in this sense, no necessary inverse relation or one-to-one correspondence between "capital intensity" and the rate of profit.

But it is equally clear that there may exist no such correspondence *even in the absence of reswitching*. Some examples of

[11] Heterogeneity of capital goods must here be understood as a difference in their technical methods of production. This would be represented by a difference in the ratio of input proportions (μ) from one technique to another. Mere physical difference would imply as well a difference in units of measurement. It would be possible to conceive of a technology in which the capital good is the same for different techniques but we need not limit ourselves to such a special case.

[12] This particular limitation would not arise in a production system where each technique has many capital goods, for different techniques are then likely to have one or more capital goods in common.

[13] The consumption good is here taken as numeraire, but we could just as well have taken units of labor.

[14] For example, take the case of a technique with a straight-line wage-profit curve ($\mu=1$) which is tangent to the frontier over two discrete segments. For any two points, each on a different segment, both price and composition effects are zero so that the value of capital is the same.

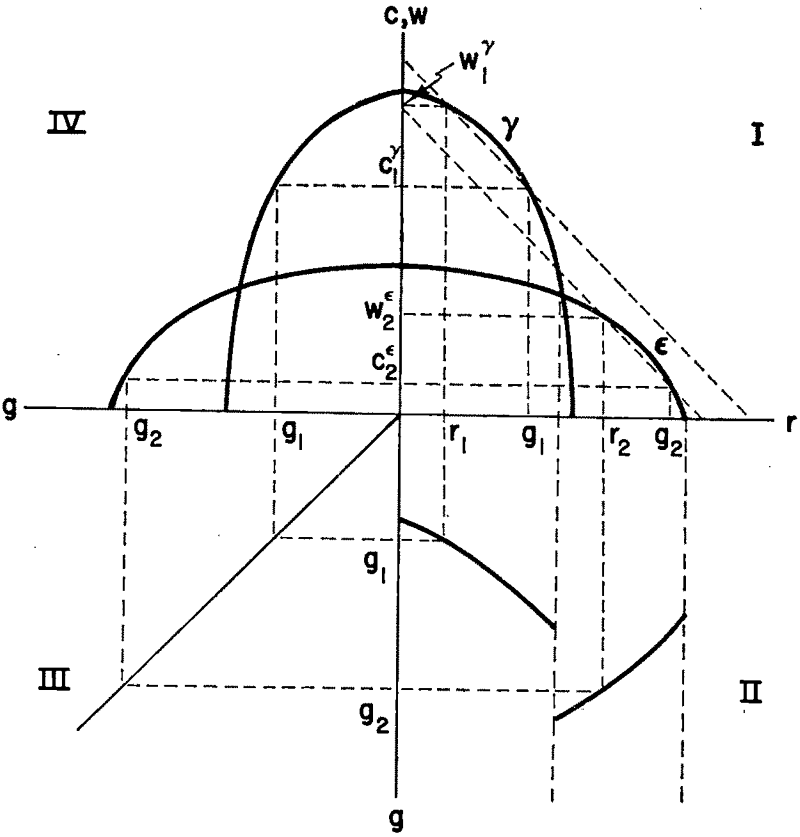

FIGURE 2

this are shown in Figures 1 and 2.[15] In Figure 1, assume a stationary state ($g=0$) so that $y=w^*$. At r_1, $k_1^\alpha=(y^\alpha-w_1^\alpha)/r_1 = \tan\theta$. At r_2, $k_2^\beta=(y^\beta-w_2^\beta)/r_2=\tan\rho$. By construction, $\tan\theta=\tan\rho$. Therefore $k^\alpha = k^\beta$. In Figure 2, assume saving behavior corresponding to the growth-profit relation shown in quadrant II. We know from the identities (13) that the value of capital per man satisfies $k=(c-w)/(r-g)$. At r_1, $k_1^\gamma=(c_1^\gamma-w_1^\gamma)/(r_1-g_1)$. At r_2, $k_2^\epsilon = (c_2^\epsilon-w_2^\epsilon)/(r_2-g_2)$. By construction, $k_1^\gamma = k_2^\epsilon$.

Two techniques may coexist, as at a switch-point. The associated equilibrium values can be identified for each technique separately using the common profit and wage rates. It will be found that the difference in the value of output per man between them will be just sufficient to yield profit at the given rate on the difference in the value of capital per man. This can be shown algebraically. By the income-accounting identity we have, for the two techniques, say α and β,

$$y^\alpha = w_0 + r_0k^\alpha, \qquad y^\beta = w_0 + r_0k^\beta$$

where w_0 and r_0 are the wage and profit rates at the switch-point. By subtraction we get

$$\frac{y^\alpha - y^\beta}{k^\alpha - k^\beta} = r_0$$

The left-hand-side of this equality is the ratio of the difference in the infinite stream

[15] The construction involved in Figure 1 is adapted from Garegnani and that in Figure 2 from Spaventa (1970).

of net output for each technique to the difference in the value of capital invested in each, output and capital being evaluated on a uniform basis in terms of the same consumption good and a common profit rate. Call this the *ratio of profitability* for the two techniques.[16] We may say in this case that the ratio of profitability is equal to the profit rate. This is a necessary implication of the condition that the two techniques are equally profitable at the given profit rate.[17]

IV. Infinite Number of Techniques

We can approach the case of an infinite number of techniques by conceptually arranging the techniques in the order in which they become eligible as r varies and by considering the coefficients of the techniques so arranged as functions of r. For this purpose we need only the coefficients v_1, b_2, μ, and the intercepts (w^*, r^*) of the corresponding wage-profit curves. Thus we write

$$(15)\quad v_1 = v_1(r); \quad b_2 = b_2(r); \quad \mu = \mu(r)$$
$$w^* = w^*(r); \quad r^* = r^*(r)$$

There is no a priori reason to expect these functions to have any particular form. Reswitching of techniques implies that the ordering is not unique. Particular restrictions can be placed on the technology so as to ensure a unique ordering. These must of necessity be arbitrary. One such condition which is sufficient but not necessary is that, for each successive technique represented on the frontier, w^* should fall and r^* rise as r rises.[18] Assuming $w^*(r)$ and $r^*(r)$ to be differentiable, this says that

$$(16)\quad \frac{dw^*}{dr} < 0, \quad \frac{dr^*}{dr} > 0, \quad \text{for all } r$$

Even with this restriction, there is no logical necessity for the coefficients v_1, b_2, and μ to vary in any particular way with r.[19] The restriction is satisfied in the special case when μ is the same *for all techniques*.

The equation of the envelope constituting the frontier can be found from the functions (15) and equation (3) for the wage-profit curve. Write this as

$$(17)\quad w = \phi[b_2(r), v_1(r), r^*(r), \mu(r), r]$$

The frontier represented by (17) is negatively sloped and may have any curvature. Thus, where differentiable,

$$(18)\quad \frac{d\phi}{dr} < 0, \quad \frac{d^2\phi}{dr^2} \gtrless 0, \quad \text{for all } r$$

[16] A ratio such as this could be computed for *any* arbitrary pair of techniques at *any* arbitrarily given profit rate. It can be computed for each pair of techniques in the entire book of blueprints from the *productivity curve* (see Appendix) constructed for that book at a given rate of profit and growth rate of the economy. In general, of course, the ratio of profitability would not be equal to the profit rate. A difference between this ratio and the profit rate is accounted for by the difference between the two techniques in the amount that would be left over from the net product for paying wages after deducting profits at the given rate on the respective values of capital. One technique is more (less) profitable than the other according as the ratio of profitability is greater (less) than the profit rate. Comparison of the profitability ratio for each successive pair of techniques with a predetermined rate of profit provides a basis for choosing the technique which is most profitable at that profit rate. When the ratio of profitability turns out to be equal to the profit rate, as at a switch-point, it is a matter of indifference which technique is chosen.

[17] Robert Solow (1967) has proposed that at a switch-point the rate of profit is also equal to the "social rate of return to saving." This proposition is further examined by Pasinetti (1969, 1970), Solow (1970).

[18] Compare Hicks, p. 154, and Michael Bruno et al. in "Symposium," p. 534. A related condition has been worked out by Brown in terms of variations in the composite coefficient v_2b_1 representing the indirect labor requirements per unit of consumption-good output.

[19] If it were to be assumed that δ is the same for all techniques, then $dr^*/dr>0$ implies $dv_1/dr<0$, so that the quantity of physical capital per unit of output in production of the capital good varies inversely with the profit rate. But no definite implication can be drawn from (16) for variation of b_2 and μ. In the special case of $\delta=0$ (the capital good lasts forever), $dw^*/dr<0$ implies $db_2/dr>0$, so that output per unit of labor in production of the consumption good varies inversely with the profit rate. Needless to say, these conditions tell us nothing about variation of the quantity of aggregate capital per man or of aggregate output per man in relation to the profit rate

Similarly, substitute the functions (15) into the growth-profit relation (12) and into equation (11) for the value of capital per man. The resulting relations may be written as

$$(19)\quad g = g[s_r, s_w, v_1(r), r^*(r), \mu(r), r]$$

$$(20)\quad k = k[b_2(r), v_1(r), r^*(r), \mu(r), g(\cdot), r]$$

The assumption of an infinite number of techniques does not necessarily imply that k and y become differentiable functions of r. However, for ease of exposition, it will be convenient to make the arbitrary assumption that these functions are continuously differentiable with respect to r. We can therefore characterize the difference between one equilibrium and another by taking the total derivatives as follows:[20]

$$(21)\quad \frac{dg}{dr} = \left[\frac{\partial g}{\partial v_1}\frac{dv_1}{dr} + \frac{\partial g}{\partial \mu}\frac{d\mu}{dr} + \frac{\partial g}{\partial r^*}\frac{dr^*}{dr}\right] + \frac{\partial g}{\partial r}$$

$$(22)\quad \frac{dk}{dr} = \left[\frac{\partial k}{\partial b_2}\frac{db_2}{dr} + \frac{\partial k}{\partial v_1}\frac{dv_1}{dr} + \frac{\partial k}{\partial \mu}\frac{d\mu}{dr} + \frac{\partial k}{\partial r^*}\frac{dr^*}{dr}\right] + \frac{\partial k}{\partial g}\frac{dg}{dr} + \frac{\partial k}{\partial r}$$

$$(23)\quad \frac{dy}{dk} = \left(\frac{d\phi}{dr} + k\right)\frac{dr}{dk} + r$$

Various components of the difference between equilibria appear from these relationships. Take the value of capital per man (k). With the technique held constant, the last two terms on the right-hand side of (22) represent, respectively, the composition effect and price effect. When the technique of production is different, there exists also a substitution effect. One might think of this as being represented by the bracketed terms in (21) and (22).[21]

Given the respective magnitudes for each equilibrium, the ratio (dy/dk) of the difference in value of net output per man to the difference in value of capital per man can be expressed in terms of the various components identified by equation (23).[22] An apparent similarity may be observed between this ratio and that which was called above the *ratio of profitability*. Nevertheless, the two should be clearly distinguished.[23] The ratio of profitability is computed for different techniques evaluated *at the same rate of profit*, reference being made either to a *switch-point* between two techniques (in which case the ratio is equal to the profit rate) or to a *productivity curve* representing all the available techniques. (See the Appendix.) It provides a way of representing the choice of technique through comparison of the ratio of profitability with the given rate of profit. In the present case, not only is the technique different, but the rate of profit is also different in the two situations compared. Moreover, this ratio is in general not equal to the profit rate. For what purpose can this ratio be used? The ratio in equation (23) has meaning only as a comparison of different growth equilibria or steady states. It can be used, so to speak, for accounting purposes, that is, to mea-

[20] It is assumed here, for simplicity, that different equilibria have the same saving proportions.

[21] When the capital good differs from one technique to another it makes no sense to compare their prices. It is therefore not economically meaningful to draw a strict separation between the difference in capital per man due to the difference in prices (the price effect) and that which is due to the technical difference in the capital good (the substitution effect).

[22] A similar formula was used by Bhaduri (1966) who called it the marginal product of capital. But, as we shall see, it can be regarded as the marginal product of capital only in a very special case.

[23] In the finite-techniques case this ratio is one of finite differences. It is expressed in terms of infinitesimal differences in the present case because of the assumption of differentiability.

sure the difference between equilibria. We may therefore call it the *accounting ratio.*

No general rule can be laid down concerning the sign and magnitude of these relations and therefore the direction of the overall difference between equilibria. The reason for this is obvious enough; it is impossible to obtain a unique form of the functions (15) that would be valid for all conceivable technical conditions. This remains so even when the sufficiency conditions (16) for absence of reswitching are assumed to hold. Particular results can be obtained under particular conditions of saving and/or technology. In the next section we consider two possible cases.

V. Some Special Cases

CASE 1:

$$s_w = 0, \quad 1 \geqq s_r > 0$$

In this case the growth-profit relation is independent of the technology. In particular, $g = s_r r$ for all r.[24] One technique may be associated with more than one profit rate due to reswitching. The variation of value of capital and net output in relation to the profit rate may take any form. It depends on the exact pattern of price, composition, and substitution effects.

If we take the special case of $s_r = 1$, this implies that $g = r$. We then get the following results.[25] By setting $g = r$ in (11), the value of capital per man at a given rate of profit becomes

$$k = \frac{\mu v_1/b_2}{\xi(r)^2} = -\frac{dw}{dr} \tag{24}$$

That is, it is equal to the slope of the wage-profit curve corresponding to the technique in use at that level of r. The same condition holds for every level of r, given the associated technique and its wage-profit curve. Since the wage-profit frontier is tangent to the wage-profit curve at every such point, their slopes are identical. It follows that, for all r

$$k = -\frac{d\phi}{dr} \tag{25}$$

Multiplying (25) by r/w leads to

$$\frac{rk}{w} = -\frac{d\phi}{dr}\frac{r}{\phi} \tag{26}$$

which defines the ratio of total profits to wages, or the distribution of net product, in terms of the elasticity of the wage-profit frontier. We also have from (25) and (18)

$$\frac{dk}{dr} = -\frac{d^2\phi}{dr^2} \gtrless 0 \tag{27}$$

which says that the value of capital may fall or rise with r depending on the curvature of the wage-profit frontier. Finally, by substituting (25) into (23) we get, for all r,

$$\frac{dy}{dk} = r \tag{28}$$

so that the accounting ratio is in this case equal to the rate of profit.

CASE 2:

$$\mu(r) = 1, \qquad \text{for all } r$$

Here the growth-profit relation becomes, for all r,

$$\begin{aligned} &g = (s_r - s_w)r + s_w r^*(r), \quad \text{if } 0 < s_w < s_r \\ &g = s r^*(r), \quad \text{if } s_w = s_r = s \end{aligned} \tag{29}$$

In either case of saving behavior, this relation is dependent on the technology through the function $r^*(r)$ which, in this case, represents the output-capital ratio

[24] Under the conditions of the Pasinetti theorem (1962), a similar relation holds without the special assumption that $s_w = 0$.

[25] Some implications of this case were pointed out by Bhaduri (1966), p. 288 and Spaventa (1970), p. 137: $g = r$ is a condition for the Golden Rule or neoclassical theorem to hold.

for the economy as a whole. Though in general nothing can be said about the form of $r^*(r)$, under the special conditions of this case we know that techniques can be uniquely ordered so that $dr^*/dr>0$ for all r. It follows that g is a continuous, monotone-increasing function of r. Thus there exists a unique relation between the growth rate, rate of profit, and technique of production over the entire range of available techniques.

By setting $\mu=1$ in (11), the value of capital per man at a given rate of profit is

$$k = \frac{v_1}{b_2} = - \frac{dw}{dr} \tag{30}$$

As in Case 1, it is defined by the technical coefficients representing the slope of the wage-profit curve corresponding to the technique in use. The results (25), (26), and (28) therefore hold also in this case. A special feature of this case is that the wage-profit curves of all techniques are straight lines. This implies that

$$k = - \frac{dw}{dr} = \frac{w^*}{r^*} \tag{31}$$

Since the condition (16) for unique ordering of techniques is fulfilled in this case, it follows that the value of capital per man is a monotone-decreasing function of the profit rate.[26]

The results of Case 2 can be readily explained. When $\mu=1$ there is no difference in the conditions of production of the two goods. Being technically the same, they can be regarded as one and the same good (except for units of measurement). Therefore their relative price is equal to unity (by appropriate choice of units) and is independent of the profit rate. This means that the price effect disappears. Furthermore, any composition of output can be produced with the same physical stock of the capital good. Thus the composition effect also disappears. There remains only a substitution effect which takes a special form. In particular, the consumption good is produced by itself and labor. All the available techniques can be ranked according to the increasing quantities of the consumption good required (as capital good) in production or according to the increasing quantity of net output of the consumption good produced. This ranking is unique and corresponds to the ordering of the techniques in relation to the profit rate. The "value" of capital per man, being equivalent to the physical stock of the consumption goods, also follows the same ordering. All of this constitutes what has come to be called the *one-commodity-model*.

[26] This case, which constitutes the basis for the Surrogate Production Function, is discussed by Garegnani (1970).

VII. The Accounting Ratio and the Profit Rate

The result that the accounting ratio (referring to two neighboring equilibria) equals the rate of profit is common to both Cases 1 and 2 and is similar to the result obtained at a switch point in the finite-techniques case. In Case 2, however, this result is susceptible of a further interpretation. Note, in particular, that in this case the difference in output per man and capital per man between two neighboring techniques consists entirely of a difference in their technical coefficients of production. The ratio of these differences (that is, the accounting ratio) is thus a technical datum independent of the rate of profit.[27]

[27] From this the possibility also arises of regarding the accounting ratio as representing the "marginal product" of the capital good itself because one equilibrium differs from another only by the addition of an infinitesimal quantity of the same capital good and by an associated increment in output of the same good. But when the capital good is different, and in the general case of many capital goods, no such interpretation is possible. For, then, the differences in capital per man and output per man can only be expressed as a value magnitude involving prices and the rate of profit.

Since it is also equal to the rate of profit it would appear, in comparing the two economies, *as if* a rate of profit existed for strictly technological reasons. Furthermore, since the profit share is equal to the elasticity of the wage-profit frontier, the distribution of income would appear to be uniquely related to the technology. These appearances would exist no matter what other explanation for the rate of profit and distribution of income might be offered by a theory relevant to the situations being compared. The technological reasons might even be made themselves to constitute such a theory. The point is, however, that those reasons and any such theory would have no applicability outside the framework of the special assumptions of this case and would therefore be, in general, of little or no interest whatsoever.

The fact that the same result (the accounting ratio equals the rate of profit) is found in Case 1 reflects the peculiar circumstances of saving behavior in that case and, beyond that, has none of the significance attached to Case 2. In particular, it does not mean that a higher value of capital is necessarily associated with a lower rate of profit. Neither is the accounting ratio susceptible of being interpreted as a technical datum which explains the rate of profit.

The common feature of both of these cases is that the value of capital is uniquely defined in terms of a technical datum.[28] The results of each case can be seen to follow directly from this condition. In the one case this condition is an accidental feature of a particular pattern of saving. In the other it is an accidental feature of a particular type of technology. Because, in Case 1, nothing further is implied concerning the technology, no general statement can be made about the relation between capital per man and the rate of profit. Because, in Case 2, a particular type of technology is assumed, there are particular implications for this relation: capital per man varies inversely with the profit rate.

There is no reason for assuming one or the other case as more likely to be found in reality than other conceivable possibilities. Indeed, in the present context, the conditions of the problem are sufficiently remote from reality to make any such statement meaningless. However, at the present level of abstraction, what we can see is that particular assumptions concerning the technology are *necessary* if there is to be an inverse relation between value of capital and rate of profit.[29] The restrictive nature of such assumptions and of the relation derived from them is evident from the fact that that relation no longer holds as soon as some slight change is made in those assumptions. Therefore, no theory based upon such foundations can lay claim to validity or generality or even to any significance as a "parable" or illustration of what exists in reality.

APPENDIX

The Productivity Curve and the Production Function

Let the profit rate be given at r_1. Then, for each technique there is a corresponding wage rate and relative price of the capital good in terms of the chosen numeraire. At a given growth rate of the system there is a corresponding physical stock of the capital good, a value of capital per man evaluated at the price corresponding to r_1 and an associated value of output per man. The values of capital and output per man obtained in this way for the entire book of blueprints form a *productivity curve*.[30] One such curve is shown in

[28] Note that, in either case, this feature is in no way related to the assumption of an infinite number of techniques. It could as well be found in a system with only one technique.

[29] In the neoclassical two-sector model (see Hirofumi Uzawa) the assumption that the consumption-good sector is the more "capital-intensive" serves the same purpose.

[30] This concept was introduced by Robinson (1956, p. 412) as an adaptation of one used by Wicksell.

Figure 3. The points α_1, β_1, γ_1, δ_1, ϵ_1, represent the values of capital and output for the available techniques at the profit rate r_1 equal to the slope of the ray r_1k. The *ratio of profitability* between techniques is the slope of the line joining two adjacent points.[31] Comparing the ratio of profitability for successive pairs of techniques with the given profit rate, we find that γ is the most profitable (it yields the highest wage rate Ow_1).

The same procedure could be carried out no matter how large the number of available techniques or the number of commodities.[32] The productivity curve (or its segments) would be positively sloped and display diminishing ratios of profitability between techniques going from left to right.[33] There is one point (or segment) to the left of which the ratio of profitability between techniques is greater than the given profit rate, to the right of which it is less. The technique(s) represented there is (are) the most profitable. The whole procedure is, in effect, a way of representing the choice of technique. It obviously does not provide a criterion for determining the profit rate for the latter is, so to say, *given in advance*.

At one profit rate (and corresponding set of prices) there is one productivity curve. At a different profit rate (say, r_2), the wage rate, relative prices of commodities and value of output and capital per man for each technique would in general be different. The productivity curve therefore has to be redrawn. Either the same or a different technique (or combination of techniques as in Figure 3) will be found to be most profitable on the new curve. The difference between the two equilibria can be analyzed in terms of the categories of price, composition and substitution effects developed in this paper.

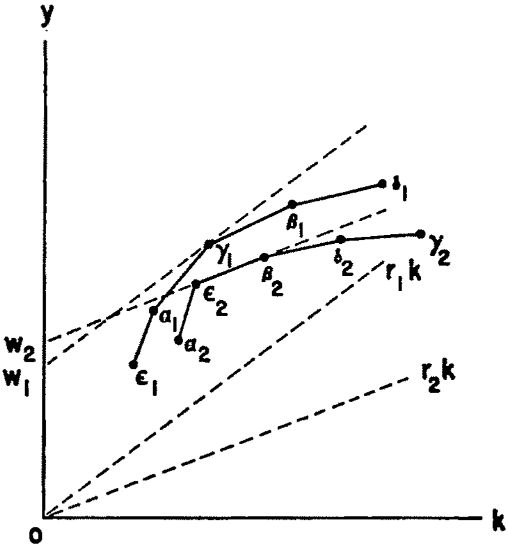

FIGURE 3

The production function relates output per man y to capital per man k, both measured in homogeneous units, such that

$$(A.1)\quad y = f(k);\quad f'(k) > 0,\quad f''(k) < 0$$

It is required that the rate of profit be equal to the marginal product of capital

$$(A.2)\qquad r = f'(k)$$

and from Euler's Theorem, we get

$$(A.3)\qquad w = f(k) - f'(k)k$$

To compare different equilibria, obtain from (A.1)–(A.3)

$$(A.4)\qquad \frac{dr}{dk} = f''(k) < 0$$

$$(A.5)\qquad \frac{dw}{dk} = -f''(k)k > 0$$

[31] The term "marginal product of investment" was used in this context by Robinson (1956, p. 412). In correspondence with the author she indicates that use of this term was misleading. On this, see Pasinetti (1969).

[32] Compare Michio Morishima, (1964), pp. 122–30. In the case of many consumption and capital goods, the relative prices would differ from one technique to another at the same rate of profit. To represent the values of output and capital for the different techniques on the same diagram the commodities must be evaluated at the same set of prices. The representation would then differ according to which set of prices is selected.

[33] This shape is a consequence of economic rationality, not of the technology. Any technique which, taken with another, had both a lower value of output and higher value of capital (that is, a negative ratio of profitability) would be irrelevant. Similarly, if between any three adjacent techniques the ratio of profitability were higher between the second and third than between the first and second, the second would be ruled out and comparison made directly between the first and third.

It follows from dividing (A.5) by (A.4) that

$$\frac{dw}{dr} = -k \tag{A.6}$$

As shown in the text, the wage-profit frontier is

$$w = \phi(r) \tag{A.7}$$

such that, where differentiable, $\phi'(r) < 0$ and $\phi''(r) \lesseqgtr 0$. (A.6) requires that

$$k = -\phi'(r) \tag{A.8}$$

Differentiating (A.8) and substituting into (A.4) leads to

$$\frac{dr}{dk} = -\frac{1}{\phi''(r)} = f''(k) < 0$$

which holds *if and only if* $\phi''(r) > 0$, that is, if the frontier is convex. If the frontier is linear or concave the production function cannot give the correct relation between k and r.

The particular case which meets the special requirements of (A.4) and (A.6) is Case 2 considered in the text, the essential feature of which is the assumption that a single homogeneous commodity (for example, corn) is consumed and used in production. The production function which describes the equilibrium relations that prevail in this case is a relation between homogeneous *physical* magnitudes. The capital or k in it is a physical quantity independent of prices and distribution. The productivity curve on the other hand, more generally relates quantities measured in *value* terms at the appropriate equilibrium prices and profit rate.

The U.S. Phillips Curve and International Unemployment Rate Differentials

By ROBERT J. FLANAGAN*

For much of the postwar period, the persistence of higher unemployment rates in the United States relative to other industrialized nations has perplexed economists and laymen alike. The earliest discussions of the problem emphasized technical differences in the measurement of the relevant statistical series, but work in the early 1960's showed that international unemployment rate differentials remained after corrections for differences in the statistical concepts and measurement (see President's Committee to Appraise Employment and Unemployment Statistics). Later studies emphasized the relative weakness of aggregate demand in the United States during most of the postwar period. The unsettling fact remained that the unemployment rates attained during the Korean War and other periods of strong demand pressure in the United States were higher than those observed abroad. A related explanation recognized the conflict of policy goals implicit in the Phillips curve and suggested that the officials responsible for monetary and fiscal policy in the United States preferred low rates of inflation by European standards. Implicit in this view was a common Phillips curve for each country and the notion that standard monetary and fiscal policies could bring the United States to European unemployment rates with no greater cost in terms of inflation. However, later evidence indicated that the tradeoffs between prices, wages, and unemployment rates differed between countries, so that the observed unemployment differentials were partially a matter of choice among conflicting alternatives, but partially the result of behavioral or structural differences which affect the position of the Phillips curve and the price change-unemployment tradeoff (see Ronald Bodkin et al.).

This paper will determine some of the main sources of the relatively "poor" Phillips curve tradeoff observed in the United States. The following sections derive some factors which may be responsible for differences in the slope and position of the curve and develop empirical estimates of the relative importance of these factors in the United States, Great Britain, and Sweden. The comparison is limited to these countries because of the difficulties in obtaining data which are sufficiently comparable to permit the conclusion that one is observing real differences rather than errors in measurement.

I Theoretical Determinants

In this section, a theory of the Phillips curve is outlined to derive parameters which govern differences in the slope and position of the Phillips curve over time and among countries. The theory generally follows the disequilibrium approach of Richard Lipsey and Bent Hansen, al-

* Assistant professor of labor economics, Graduate School of Business, University of Chicago. I wish to thank Bent Hansen, Lee Soderstrom, Lloyd Ulman, the managing editor, and an anonymous referee for useful criticism and suggestions on earlier drafts. This paper was prepared under Grant No. 91-05-68-70 from the Manpower Administration, U. S. Department of Labor, under the authority of title I of the Manpower Development and Training Act of 1962 as amended, but points of view which are expressed do not necessarily represent the official position or policy of the Department of Labor.

though comparisons to more recent neoclassical formulations are made where appropriate.

The familiar dynamic hypothesis underlying the present approach is that the rate of change of wages is proportional to the magnitude of the labor market disequilibrium, defined as the rate of excess demand. Thus

$$(1) \qquad \Delta \frac{W}{P} = k\left(\frac{D - S}{S}\right)$$

where $\Delta(W/P)$ is the time rate of change of real wages, D and S are the demand and supply of labor, respectively, and k is the reaction coefficient denoting the flexibility of wages in response to a given disequilibrium in the labor market. The appropriate measure of $[(D-S)/S]$ in the labor market is the job vacancy rate, V, minus the unemployment rate, U, where vacancies are defined as the difference between the demand curve (desired employment) and actual employment, and unemployment as the labor supply minus actual employment. However, in most empirical work a relation between the vacancy rate and the unemployment rate is postulated, and the unemployment rate is used as a proxy for excess demand. Movements along the unemployment-vacancies (UV) curve correspond to cyclical changes in the rate of excess demand, while shifts in the position of the curve correspond to shifts in the degree of structural maladjustment in the labor market.[1] Both k, the coefficient indicating the flexibility of wages in response to labor market disequilibrium, and the degree of "structural maladjustment" in the labor force will influence the position of the Phillips curve. The interpretation of structural maladjustment is elaborated in the following sections.

1. *Turnover*

Given the definitions of unemployment and vacancies, the parameters of the UV relation reflect the speed and extent of adjustment of actual to potential employment and actual to potential labor supply when the labor market is in disequilibrium. The study of this process is facilitated by disaggregating the stocks of unemployment and job vacancies into the flow per unit of time and average duration of each variable. Thus, the job vacancy and unemployment rates can be defined

$$(2) \qquad \begin{aligned} V &\equiv I_v D_v \\ U &\equiv I_u D_u \end{aligned}$$

i.e., as the product of the weekly incidence of new unfilled vacancies (unemployment) as a percentage of the labor force and the average number of weeks such vacancies remain unfilled (individuals remain unemployed). The identities define a steady state in which the weekly flows of new vacancies and new unemployment exactly match and replace the vacancies and unemployment generated (on average) D_v and D_u weeks earlier. The distinction is important in part because the determinants of the flow and duration of each stock are sufficiently diverse that the appropriate policies to reduce an observed stock of unemployment are not obvious a priori.[2]

[1] Prior to the appearance of the first Phillips curve, this relation was postulated and studied by J. C. R. Dow and L. A. Dicks-Mireaux who argued that frictional vacancies (at very low levels of demand) and frictional unemployment (at high levels of demand) will generate a non-linear relation. Lipsey applied a similar argument, and Edmund Phelps derives the same form from an argument based on labor turnover behavior. Jacob Mincer accepted the hyperbolic form and pointed out that movements along the UV curve coincide with movements along the Phillips curve. Empirical studies in Great Britain, Sweden, Australia, and the Netherlands (using data which are subject to the qualifications mentioned in the text) have uncovered highly significant non-linear relations between the aggregate level of vacancies and unemployment (see references in Hansen and Phelps).

[2] The distinction is also useful because it highlights the possibility that in tight labor markets an accelera-

When desired employment exceeds actual employment, the rate of incidence of vacancies is defined as

$$(3) \quad I_v = q(Q) + y(Q) + r + \Delta E^*(Q)$$

in which q is the quit rate, y the layoff rate, r the retirement rate, ΔE^* is the change in desired (cost minimizing) employment as a percent of the employed work force, and Q is the rate of excess demand in the product market. The rate of incidence of unemployment reflects the combined influence of quits, layoffs, and labor force entries, or

$$(4) \quad I_u = \alpha q(Q) + \beta y(Q) + \gamma p(Q)$$

in which p is the rate of gross labor force entrance, and α, β, and γ are parameters representing the propensity of each source of turnover to incur unemployment. From these definitions it can be shown that the disequilibrium behavior of the flows of new vacancies and new unemployment is not predictable in advance.

$$(5) \quad dI_v/dQ = q' + y' + \Delta E^{*\prime} \gtreqless 0$$

where q', $\Delta E^{*\prime} > 0$ $y' < 0$

$$(6) \quad dI_u/dQ = \alpha q' + \beta y' + \gamma p' \gtreqless 0$$

where $p' > 0$

The specified signs reflect considerable empirical evidence that voluntary frictions are positively related to excess demand in the product market while friction motivated by corporate maximizing decisions is negatively related to excess demand in the product market. It is clear that the disequilibrium behavior of I_v and I_u is theoretically ambiguous because of the opposing cyclical behavior of the underlying turnover flows. The results will depend on the relative strength of the (positive) cyclical elasticity of quits and entrants on the one hand and the (negative) cyclical elasticity of layoffs on the other, as well as the proportion of quits, layoffs, and labor force entrants which incur some unemployment.

2. *Duration of Unemployment and Vacancies*

Most of the cyclical variance in unemployment and vacancy rates is due to cyclical variations in the average duration of unemployment and vacancies D_u and D_v. However, there is some theoretical controversy concerning the proper interpretation of the observed phenomena. On the one hand, the cyclical sensitivity of D_u can be treated as an index of the severity of "structural" imbalances in the labor market which prevent the matching of workers and jobs. On the other, the duration of unemployment or vacancies (and thus the unemployment and vacancy rates) has been treated as search-related and hence voluntary.[3] Both formulations yield the same predictions concerning the cyclical behavior of longer term unemployment and vacancy rates. Therefore,

$$(7) \quad D_v = h(Q) \qquad h' > 0$$

$$(8) \quad D_u = j(Q) \qquad j' < 0$$

Thus the slope of the UV relation depends critically on the cyclical sensitivity of quits, layoffs, and labor force entrants, the proportion of each turnover flow which incurs unemployment, and the cyclical behavior of the duration of vacancies and unemployment. These same variables influence the slope and curvature of the Phillips curve, for as other writers have

tion in job-changing and labor force entry could increase the flow of new unemployment sufficiently to offset the effects of the falling average duration on the total unemployment rate, thus inducing a positive slope in the UV relation and the Phillips curve (see Bernard Corry and David Laidler). The empirical importance of this possibilty is assessed below.

[3] The equilibrium duration of unemployment (optimal duration of search) comes out of the theory of information as developed by George Stigler. More recently the theory has been recast to generate cyclical variations in D_u and D_v (see papers in Phelps et al.).

pointed out, the steeper or more curved the UV relation, the greater the change in excess demand $(V-U)$ and hence $\Delta(W/P)$ associated with a one unit change in the unemployment rate (see Hansen, Lipsey). Moreover, as indicated by the constant term, the position of the UV curve is also a function of the general level of turnover in the economy. Therefore, both the level and cyclical fluctuation in the turnover flows can be an important determinant of the slope and position of the Phillips curve and a fortiori an important source of international unemployment differentials.

3. *Expectations*

Although the theory of labor disequilibrium traced out in earlier sections is a theory of dynamic adjustments in real wages, the dependent variable in most Phillips curve studies is the rate of change of money wages. It is therefore necessary to include a variable which captures reactions to anticipated price increases.[4] Economists who emphasize the role of expectations in the wage determination process conclude that while a stable disequilibrium wage adjustment relation may be observed in the short run, there is no long-run tradeoff available to the economy, for the system will move back to an "equilibrium" rate of unemployment via one of several postulated mechanisms.[5] From this theory it follows that an unemployment rate which is lower than the equilibrium rate can be maintained by the application of monetary and fiscal policies only at the cost of an ever-accelerating rate of inflation as expectations and hence wage demands are constantly revised on the basis of price changes in current and previous periods.[6]

This argument has definite testable implications for the position of the *short-run* Phillips curve which have been stated clearly in this *Review* by Friedman:

> Stated in terms of the rate of change of nominal wages, the Phillips Curve can be expected to be reasonably stable and well defined for any period for which the *average* rate of change of prices, and hence the anticipated rate, has been relatively stable. For such periods, nominal wages and "real" wages move together. Curves computed for different periods or different countries for each of which this condition has been satisfied will differ in level, the level of the curve depending on what the average rate of price change was. The higher the average rate of price change, the higher will tend to be the level of the curve. [p. 9, fn. 5]

Since expected price increases are postulated to exert an independent influence on wage changes, the wage equation must be amended to include a separate expectations variable.

II. Aggregate Wage Changes in Sweden, Great Britain, and the United States

The objective of this section is to estimate aggregate wage change equations in each of the sample countries, to document differences in the slope and position of the Phillips curves for these three countries, and to offer some tentative judgements on the influence of price expectations and trade unions on the position of Phillips curves. The equations for each country are estimated on comparable quarterly data for the period 1951: II through 1968: IV by ordinary least squares. The dependent variable for each country is the rate of

[4] Unanticipated price increases will work through their influence on the rate of excess demand variable.

[5] The theoretical arguments and alternative methods of adjustment are specified in Milton Friedman and the papers in Phelps et al. In his introduction to the latter reference, Phelps admits the possibility of a long-run tradeoff which is nevertheless steeper than observed short-run relations.

[6] Others have argued that the maintenance of high demand will work out structural rigidities in the economy and that rising prices resulting from lower than equilibrium unemployment rates may erode the effect of institutional and legal constraints which impede employment, thus tending to reduce the equilibrium rate.

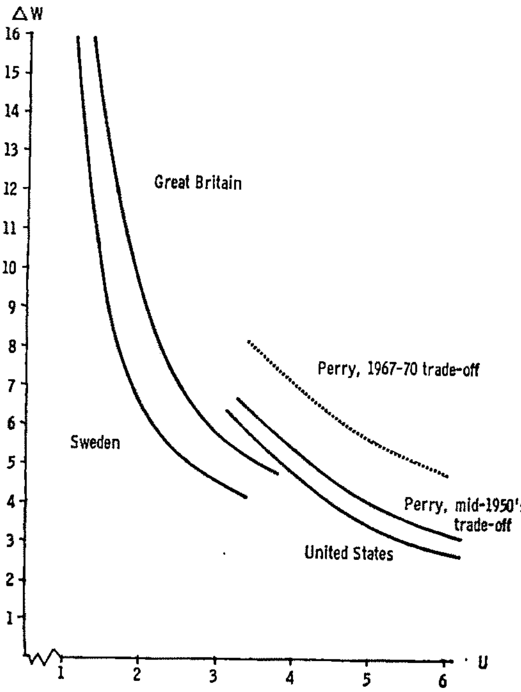

FIGURE 1. ESTIMATED PHILLIPS CURVES SWEDEN, GREAT BRITAIN. UNITED STATES, 1951–68

change of gross hourly earnings, which normally increases more rapidly than the rate of change of negotiated hourly wage rates because of the influence of overtime payments and wage drift.[7] Moreover, the unemployment rate in each country is adjusted to the concepts and measurement of the *U.S.* sample survey series.[8] The rate of change of the Consumer Price Index is used in the current period, lagged one quarter, and in an Almon distributed lag to capture the effect of anticipated price changes.[9]

In the subsequent regressions, ΔW is the four-quarter rate of change of earnings, ΔP is the four-quarter rate of change in the Consumer Price Index, and U is the average unemployment rate over the past four quarters. This form, which centers U about $1\frac{1}{2}$ months behind the ΔW variable, was found to perform best. The term Z is the sum of the coefficients of a distributed lag of past price changes and is included as an alternative to ΔP to test the proposition that workers obtain full compensation for price increases, but with a lag.[10]

The wage adjustment equations which were selected after experiments with alternative lag structures appear in Table 1, and the tradeoffs which these regressions imply are drawn in Figure 1.[11] For the

[7] The sectors covered by the earnings data differ between countries: the *U.S.* data are for the manufacturing sector, the Swedish data are for mining and manufacturing, and the British data are for the above plus construction, utilities, transportation, communication, and public administration. Sources are U.S. Bureau of Labor Statistics, Ministry of Labour *Gazette*, and *SCB, Allmän Månadsstatistik*. The British data are from a semiannual series which has been interpolated for intervening quarters.

[8] Unemployment data differ largely because many European series are by-products of unemployment insurance or employment service programs and tend to understate unemployment and the unemployment rate relative to sample survey data. A full analysis of these differences is included in the President's Committee to Appraise Employment and Unemployment Statistics. Since late 1961 a Swedish quarterly sample survey has provided unemployment rate estimates which closely correspond to *U.S.* concepts and measurement (see *SCB*, 1969). Estimates for earlier years were developed by linking the survey series to insurance and trade union series. For Great Britain a comparable unemployment rate series was developed by using Census and special survey materials to estimate the undercount of women and other groups in the official registration series (see U. K. Ministry of Labour *Gazette*). Details on the adjustments are in Flanagan, Appendix, and may be obtained from the author.

[9] Since indirect taxation has been an important component of Swedish fiscal policy in the 1960's, the Swedish regressions were tried with two price series—the rate of change of the total consumer price index and the rate of change of the net price index (see *SCB*, 1968). The latter excludes the effects of indirect taxes and differs from the former index only since 1959. There was no significant difference between the coefficients obtained from the alternative series.

[10] The reported results, selected after considerable experimentation, are for polynomials of degree 4, 3, and 5 fit to lags of 8, 5, and 12 quarters for the United States, Great Britain, and Sweden, respectively.

[11] The tradeoffs were generated under steady-state assumptions by substituting a price change equation (in which the rate of change of hourly earnings ΔW and import prices ΔI are related to the rate of inflation) for each country into the wage change equation with a single period rate of price change. The price change equations are:

TABLE 1—QUARTERLY EARNINGS CHANGE REGRESSIONS, SWEDEN, GREAT BRITAIN, UNITED STATES, 1951: II—1960: IV[a]

Country	Regression No.	Constant	Regression Coefficients						R^2	d
			U^{-1}	U^{-2}	ΔU	ΔP	ΔP_{t-1}	Z		
Sweden	1.	2.04		7.81 (2.03)[b]			.80 (.09)[b]		.78	1.08
	2.	3.39		3.27 (1.72)				.96	.82	.86

United States, wage equations were estimated alternately using the U^{-1} and U^{-2} forms of the unemployment variable. Although there were no statistical grounds for favoring either specification over the other, the equation using U^{-1} is used to construct the tradeoff in Figure 1 to facilitate comparison with a recent study by George Perry. The tradeoffs derived by Perry, using somewhat different definitions of W and U, are included in Figure 1 and discussed below. On the other hand, the wage equation using the U^{-2} specification was required to conduct a test for structural independence of the wage equations for each country and is reported in regression 8. When a Chow test was applied, the computed F-ratios were above the critical value for each pair of countries, and the hypothesis that the observed differences in wage adjustment relations are the result of sampling variations was rejected (see Gregory Chow).[12]

Given the structural independence of the estimated Phillips curves, the regressions and the curves they generate appear to justify the following conclusions:

1) Over the range of observations provided by the 1951–68 period, the United

Sweden: $\Delta P=.77+.36\ \Delta W+.23\ \Delta I$
Great Britain: $\Delta P=-.12+.58\ \Delta W+.12\ \Delta I$
United States: $\Delta P=-.33+.58\ \Delta W+.12\ \Delta I$

All coefficients are significant at the 1 percent level. Alternative assumptions about the value of ΔI had a miniscule impact on the tradeoffs.

[12] The computed F-ratios are 10.15 for the United States and Sweden, 7.04 for the United States and Great Britain, and 7.49 for Great Britain and Sweden. The critical value was 3.82.

States experienced the least favorable Phillips curve. However, if one extrapolates the curves for the European countries, it appears that at unemployment rates over 4 percent, Great Britain and eventually Sweden would have experienced more wage inflation than the United States. This reflects the relatively high rate of autonomous wage increases in the two European nations as noted below. The conclusion of a relatively "inferior" *U.S.* tradeoff at lower unemployment rates is strongly reinforced by a comparison with the Phillips curve recently derived by Perry for the mid-1950's. For most of the period covered by the present study, Perry's estimates, which weight each member of the labor force by the relative hours and income received in the relevant age-sex cell, imply that a given ΔW is associated with about one-half of 1 percentage point more unemployment than the Phillips curve derived from regression 6. Moreover, for the period since 1967, Perry's work indicates that a shift in the composition of the labor force toward high unemployment groups has shifted the *U.S.* Phillips curve still further from European experience over the full range of postwar unemployment rates. The evidence supports the conclusion that the relatively high postwar unemployment rates in the United States reflected a less favorable tradeoff available to monetary and fiscal policy as well as the maintenance of a greater gap between actual and potential output.

2) Autonomous wage changes, as reflected in the constant term, appear to be higher in both Great Britain and Sweden than in the United States. (For the United States, the appropriate comparison is with regression 8. Measurement is not sufficiently precise to distinguish between autonomous wage pressure in Great Britain and Sweden. This weakens the hypothesis that the relatively unfavorable Phillips curve for the United States may be attributed to relatively great *autonomous* power of *U.S.* unions on wage changes. This, of course, is not to argue that the unions play no role in the problem, for their presence may be felt in the speed of wage adjustment, the relation between unemployment and vacancy rates, or the reaction of wages to price changes. Moreover, the constant terms in Table 1 will also reflect in part the constant term of the UV relation which can vary between countries and thus obscure differences in autonomous institutional wage pressures.

3) A second possible explanation for the relatively poor position of the *U.S.* Phillips curve is that the average rate of price inflation and/or the reaction of wages to price changes has been relatively high in the United States. During 1951–68 the average annual rate of change of prices was 4.3 percent in Sweden, 3.9 percent in Great Britain, and 2.3 percent in the United States. Thus, the hypothesis by Friedman noted in Section I does not explain the ranking of this set of Phillips curves. Indeed, the ranking of both the average rates of inflation *and* the sums of the distributed lag coefficients are exactly *inverse* to the average rate of price inflation over the period Nevertheless, the coefficients on the price change variables in this limited sample may provide some very tentative support for the accelerationist hypothesis. Under this hypothesis accelerating wage or price inflation is predicted only when aggregative policies are used to *maintain* an unemployment rate below the equilibrium rate for some period of time. Most industrialized nations have experienced sufficiently frequent cyclical fluctuations that they have not been able to generate data which would test this hypothesis persuasively. Sweden, however, provides a possible exception as the low and narrow range of unemployment rates indicates. In Table 1, the coefficient on the price change vari-

able is highest in Sweden, and when the distributed lag variable is used, the sum of coefficients was just above or just below unity in several instances (see regression 2 for example). Thus, institutional efforts or ability to protect real wages against the eroding influence of price increases are strongest in Sweden where the average rate of inflation has been highest among the countries in this sample (and where the Phillips tradeoff has been most favorable).

III. The Slope and Position of the UV Curve

It is clear from the empirical work in the previous section that neither autonomous wage changes nor expectational forces are responsible for the *relative* position of the *U.S.* Phillips curve. Thus the burden of explaining the international differences falls on the coefficient of the unemployment rate which is a hybrid of the wage flexibility coefficient and the forces influencing the position of the UV relation. Our attention will be limited to the hypothesis that the UV relation is relatively high in the United States. If comparable unemployment and vacancy data were available, a straightforward test of this proposition would be possible. However, job vacancy data are obscure or shaky for some countries, and regressions of the vacancy rate on the unemployment rate can at most show that the UV relation for the United States is displaced relatively far from the origin but will not yield information on specific characteristics of disequilibrium behavior in the labor market which are responsible for the finding. Since the possibilities are quite diversified and have different policy implications, the procedure in the subsequent empirical work will be to examine separately the factors which are shown to determine the UV relations.

1. *The Incidence of Unemployment*

The weekly flow of new unemployment is almost twice as high in the United States as in Great Britain or Sweden. Over the postwar periods for which data are available the average annual I_u are .63 for the United States, .33 for Great Britain, and .31 for Sweden. (The small size of these rates tends to obscure the massive flows they represent. At recent labor force levels the data imply that on average, four hundred seventy thousand people became unemployed each week in the United States. The comparable figures for Great Britain and Sweden are eighty-two thousand and twelve thousand.) This finding is a considerable surprise, both because it indicates that the incidence of unemployment may be responsible for most of the observed international differences in the unemployment rate[13] and because most nonmacroeconomic labor market policy during the past decade has emphasized the reduction of unemployment and unemployment differentials via programs which are largely designed to reduce the duration of unemployment.

Reference to equation (4) indicates that the relatively high I_u that characterizes labor market equilibrium in the United States must result from higher turnover flows, a lower level of labor market efficiency in the sense that a larger proportion of each turnover flow may incur unemployment in the United States,[14] or a labor

[13] Using 1965 data and the steady-state definition given by equation (2) we may divide the *U.S.* 1965 unemployment rate by the rate of incidence of unemployment for that year to obtain an estimate of the average duration, 7.3 weeks. This average duration may be multiplied by the observed 1965 rate of incidence in Great Britain and Sweden to obtain the aggregate unemployment rates estimated to prevail *if* the average amount of time between jobs was the same (7.3 weeks) in each country. For Great Britain the estimate is 2.2 percent and for Sweden the estimate is 1.8 percent—in each case quite close to the observed rate for the year.

[14] The use of the word "efficiency" is intended to include the possibility that the stock and quality of labor market information is sufficiently imperfect or the cost of search is sufficiently low that a larger fraction of gross turnover in the United States finds unemployed search behavior rational.

TABLE 2—WEEKLY FLOW OF NEW UNEMPLOYMENT AS PERCENT OF LABOR FORCE, UNITED STATES, 1970

Occupation	I_u	Industry	I_u

force structure in which sectors with high turnover in all economies are relatively important. In the remainder of this section, these alternative possibilities will be assessed.

It is clear from the data in Table 2 that the composition of the labor force has little influence on the relatively high flow of new unemployment in the United States. In virtually all sectors I_u substantially exceeds the aggregate value for Great Britain and Sweden, so that even if each country had the same industrial and occupational structure, I_u would be relatively high in the United States. As it turns out, the actual structural differences are minor. Moreover, these findings cannot be "explained" by the racial heterogeneity of the *U.S.* labor force. Although the weekly rate of new unemployment is much higher among nonwhites—for males, it was responsible for the full racial difference in unemployment rates in 1970—the I_u for whites (.42 for males and .70 for females in 1970) is still significantly above the average rates recorded abroad.[15]

[15] Data for the computations supporting these statements are from Flaim and Schwab.

On the other hand, the data in the bottom panels of Table 2 indicate that women and teenagers are the main source of the relatively high I_u in the United States. The rate of new unemployment for males with a primary attachment to the labor force is no higher than the average I_u observed abroad. Thus, if women and teenagers were a relatively large proportion of the *U.S.* labor force, the high amount of turnover-related unemployment could be explained. However, the demographic composition of the labor force in each of the countries under study is quite similar. During the late 1960's, youth (14–24 years) constituted about 20 percent and females 35–40 percent of the labor force in each country. (See *OECD*, 1968.) Moreover, the demographic differences in I_u reflect more than the racial composition of the various demographic groups. If one assumes (with strong support from the labor force survey data) that the average duration of unemployment is the same for both races, it is possible to compute the probable I_u for each of the age-sex cells in Table 2 for an all-white labor force. But with this adjustment for racial hetero-

geneity, the aggregate I_u falls by only .035 percent of the labor force. In the absence of evidence that labor force structure accounts for the large flow of new unemployment in the United States, turnover and labor market efficiency are examined below.

There is some direct evidence that the turnover flows are larger in the United States. During the postwar years for which data are available, the average monthly separation rate was 4.3 percent in the United States, 2.5 percent in Sweden, and 2.6 or 3.5 percent in Great Britain, depending on the series chosen.[16] Thus, even if the α, β, and γ coefficients are the same in each country, the incidence of unemployment would have been greater in the United States, neglecting the unlikely possibility that the gross labor force entry rate (which is not recorded in the two European countries) was sufficiently lower in the United States to offset the higher separations rate.

The reasons for the differences in turnover rates are not easy to isolate. Although there have been predominantly qualitative discussions of widespread labor hoarding and employer paternalism in many European countries and assertions that the United States has a "more mobile" society, these and a number of alternative economic explanations of higher American turnover rates cannot be tested carefully in the absence of quit and layoff data for European countries. On a more descriptive level, one would expect relatively rapid shifts in the structure of employment demand and relatively wide annual seasonal fluctuations to induce relatively high turnover rates. Structural shifts in demand will have a direct influence on layoffs as well as an indirect influence on the level of quits, for rapid structural change implies a relatively rapid obsolescence of job information and thus a greater expected return to repeated information search.

An index of structural change was computed using employment data for nineteen two-digit manufacturing sectors.[17] By this measure, the United States did experience more structural change than Great Britain and Sweden during the 1951–60 period. However, during the 1960's, the same measure indicates that Sweden experienced considerably more structural change than either the United States or Great Britain, although, as Table 2 indicates the *U.S.* I_u and separations rate were still relatively high during this period despite less structural change. When the annual variance of monthly seasonal adjustment factors for unemployment is used to measure seasonality over the period 1956–67, the average annual variance is 1780 for Sweden 103 for the United Kingdom, and 113 for the United States.[18] This evidence also is not

[16] For the United States and Sweden, the data cover the mining and manufacturing sector (see U.S. Bureau of Labor Statistics and Statistiska Centralbyrån). The lower British estimate is from the British Ministry of Labour series which excludes people who begin and end their employment within a given month, so that the series understates the separations rate as it would be measured in the United States and Sweden. The second British series, unpublished but compiled by the Inland Revenue Department, refers to the total number of separations within the field of pay-as-you-earn income tax divided by the number of jobs in that category. Although the coverage of this series is therefore broader than the American and Swedish data, the bias, if any, is unclear, for it includes high turnover sectors such as construction along with the civil service.

[17] The index of structural change used in the regressions as a measure of long-run shifts in demand is

$$B = \sum_{i=1}^{8} \mid \Delta E_{it} - \Delta E_t \mid \frac{E_{it}}{E_t} (100)$$

where E_t = total employment in year t
E_{it} = employment in industry i in year t
ΔE_{it} = the rate of change of employment in the ith industry in year t
ΔE_t = the rate of change of employment for all industries

The index of structural change is computed from annual data on total employment in eight one-digit industrial sectors obtained from *OECD*, 1964, 1968.

[18] The numbers were computed from unpublished data supplied by the U.S. Bureau of Labor Statistics and the *OECD* Statistical Office.

TABLE 3—RATE OF INCIDENCE (I_u) REGRESSIONS, UNITED STATES, GREAT BRITAIN, SWEDEN

fully consistent with the ranking by labor turnover.

2. *The Cyclical Sensitivity of New Unemployment and New Vacancies*

In the absence of data on quit, layoff, and gross labor force entry rates for each country, the labor market efficiency parameters cannot be directly determined. However, some indication of their relative magnitude is possible from an analysis of the cyclical behavior of I_v and I_u, which itself is germane to the position of the UV and Phillips curves.

The cyclical sensitivity of I_u is described by the estimates in Table 3. The regressions in Table 3 are on generally comparable annual data, although the number of observations is small and the degrees of freedom problem is particularly severe for Sweden. Since the rate of unemployment, U, is used as a proxy for Q, direct estimates of the cyclical coefficients may be biased, because I_u is a behavioral function of the unemployment rate (used as a proxy for excess demand) as well as one of its determinants (see equation (2)). Therefore, reduced form estimates in which $I_u = f(N_u)$, where N_u is the number of people unemployed longer than one week as a percent of the labor force, are included with the direct estimates in Table 3. Finally, both linear and non-linear relations were tested, but the reported linear relations performed best.

Regressions 9, 12, and 15 provide comparable estimates when the effect of all other influences is assumed to be in the constant term.[19] In Great Britain and Sweden the incidence rate varies directly with the unemployment rate, indicating that changes in new unemployment are

[19] Similar estimates can be computed from the reduced form regressions 11, 14, and 16.

more closely associated with changes in layoffs than with changes in quits or labor force entry. In the United States, however, the rate of incidence is not significantly related to the rate of unemployment, indicating that in tight labor markets the decline in new unemployment associated with a reduction in layoffs is offset by a rise in the flow of new unemployment associated with the (increasing) voluntary flows of quits and labor force entrants.

It has been suggested that with strong demand pressure the unemployment induced by a rising quit rate could increase sufficiently to generate a positively sloped section in a Phillips curve (see fn. 2). However, for this result to obtain, 1) the percent of the labor force unemployed through "voluntary" choices, U_V, should be negatively related to the percent of the labor force unemployed because of layoff, U_L, and 2) the absolute value of the coefficients on U_L must be greater than unity. The evidence indicates that these conditions do not hold for the United States. A regression on quarterly data for the period 1967: II (when these series were first published) through 1970: IV yields

$$\begin{aligned} U_V = \underset{(.150)}{1.448} + \underset{(.085)}{.557}\, U_L - \underset{(.106)}{.373}\, \text{DUM1} \\ + \underset{(.095)}{.156}\, \text{DUM2} + \underset{(.096)}{.384}\, \text{DUM3} \\ R^2 = .87 \end{aligned}$$

when quarterly dummies are included. Clearly the hypothesis fails, for the sign indicates that the voluntary unemployment rate varies directly with the involuntary rate. Whatever the influence of voluntary turnover on the rate of new unemployment, these flows are more than offset by the falling average duration of unemployment in tight labor markets.[20]

The remaining regressions in Table 3 were run to isolate specific noncyclical determinants of the incidence of unemployment. These determinants should reflect variations in employment and labor force entry which are independent of movements in aggregate demand. If there are marked year to year changes in these indices which are largely independent of cyclical fluctuations, their influence should be reflected in a time-series regression. The indicators of noncyclical factors affecting the amount of turnover during the course of a year are an index of changes in the industrial composition of demand (see fn. 17) and the seasonal variance of unemployment over the year.

Regressions 10 (for the United States) and 13 (for Great Britain) are run on this data. In each equation, the role of the unemployment rate is unchanged, although it is now measured with less precision in the case of Great Britain, and the index of structural change is not significant. The coefficients on the index of seasonality are negative in both cases and measured with considerable precision in the case of the United States. This is the opposite of the expected effect and the reason for it is not immediately clear.

We are left with two salient differences between the United States and the sample European countries: the weekly flow of unemployment is relatively high and cyclically insensitive in the United States. From equation (4) it is clear that the level of I_u depends on the size of labor turnover flows and the proportion of each incurring some unemployment. Also, from equation

[20] For example, the quit rate, QR, is *negatively* related to unemployed quits as a percent of the labor force, U_Q.

$$\begin{aligned} U_Q = \underset{(.103)}{1.020} - \underset{(.050)}{.210}\, QR - \underset{(.037)}{.012}\, \text{DUM1} \\ - \underset{(.037)}{.012}\, \text{DUM2} + \underset{(.072)}{.318}\, \text{DUM3} \quad R^2 = .76 \end{aligned}$$

Data for this regression and the one in the text are from U.S. Bureau of Labor Statistics.

TABLE 4—SEPARATIONS RATE REGRESSIONS, UNITED STATES, GREAT BRITAIN, SWEDEN

Country and Time Period	Regression Number	Constant	Regression Coefficient U	R^2	d
United States (1951–66)	17	5.62 (.31)[a]	−.28 (.06)[a]	.57	1.10
Great Britain (1951–66)	18	3.11 (.17)[a]	−.19 (.06)[a]	.41	.86
Sweden (1958–68)	19	3.90 (.20)[a]	−.71 (.10)[a]	.85	1.30

Sources: U.S. Bureau of Labor Statistics, 1968; Ministry of Labour *Gazette;* Konjunkturinstitutet.

[a] Significant at the 1 percent level.

(6) it is clear that where

$$\frac{dI_u}{dQ} < 0 \text{ as in Great Britain and Sweden:}$$

$$|\alpha q'| + |\gamma p'| < |\beta y'|$$

$$\frac{dI_u}{dQ} = 0 \text{ as in the United States:}$$

$$|\alpha q'| + |\gamma p'| = |\beta y'|$$

Therefore, if the labor market efficiency parameters are the same in all countries, i.e., $\alpha=\beta=\gamma$, the involuntary elasticity must exceed the voluntary elasticity in European countries.

However, this inference is contradicted by Table 4, which reports the results of regressions of the separations rate on the unemployment rate. In each country, the coefficient on the unemployment rate is negative and measured with high precision, indicating that quits are more sensitive to cyclical variations than layoffs. It is clear, therefore, that the labor market efficiency parameters are not equal. It is also clear that the relatively high *U.S.* separations rate cannot be explained by a relatively weak pressure of demand. Reductions in the unemployment rate to common European levels would further increase the separations rate. The inverse relation between the separations rate (vacancy incidence rate) and the unemployment rate is strongest in Sweden, indicating that the cyclical sensitivity of quits relative to layoffs is greatest there.

If either the quit or layoff elasticity were known for each country, the other could be determined from the coefficients in Table 4. As noted above, there is considerable qualitative evidence indicating that layoff elasticities are relatively high in the United States. One indication of differences in the cyclical variation in layoffs among countries is the speed with which employment adjusts to changes in output, and employment adjustment coefficients estimated by Frank Brechling and Peter O'Brien from postwar data for several countries support this view. The values of the employment adjustment coefficient (.590 for the United States, .219 for the United Kingdom, and .285 for Sweden) indicate that y' is two to three times greater in the United States. Thus the layoff elasticity in the United States is two to three times that observed in Europe.

If one assumes that the employment adjustment coefficients represent the *relative* size of y' in each country, the actual value for each country can be determined if the cyclical layoff elasticity can be deter-

mined in any one of the countries. Direct estimation is possible in the United States, and regression of the layoff rate on the unemployment rate for the period 1951–68 yields an estimate of $y'=.29$, which implies a y' of .11 in the United Kingdom and .13 in Sweden.

Once y' is determined for each country, q' can be inferred from the fact that the regression coefficients on the unemployment rate in Table 4 should approximate $(q'+y')$. Applying this formula yields estimates of q' of $-.45$ for the United States, $-.39$ for Great Britain, and $-.70$ for Sweden. Since q' is found to be greater than y', the main difference in the cyclical sensitivity of I_u is to be found in the proportion of voluntary and involuntary turnover which incurs unemployment. For Sweden and Great Britain:

$$|\alpha q'| < |\beta y'| - |\gamma p'| \tag{9}$$

and for the United States:

$$|\alpha q'| = |\beta y'| - |\gamma p'| \tag{10}$$

Since we know that q' exceeds y' for each country, unemployment due to quits must be less than unemployment due to layoffs, so $\alpha<\beta$ is required.

We have said very little about labor force entry and reentry as yet. Unfortunately, data on gross labor force flows, the variable of main relevance here, are scarce both in the United States and abroad. If one assumes that gross and net labor force flows are correlated, and there is some fragmentary evidence in support of this proposition for the United States,[21] then p' should vary directly with the size of the labor force participation elasticity. Evidence for the three countries under study indicates that the labor force elasticity is highest in Sweden and lowest in the United States. (See Flanagan.) In terms of equations (9) and (10), this result reinforces the conclusion that a higher fraction of voluntary turnover flows in the United States than in Europe must incur unemployment.

To summarize the findings of the past two sections, the level of the incidence of unemployment is higher in the United States in part because the underlying turnover flows are higher irrespective of cyclical conditions and in part because the proportion of voluntary turnover flows incurring unemployment appears to be higher in the United States. It is not clear with the available data whether the high turnover rate is due to a relatively high quit rate, layoff rate, or both. There is qualitative evidence indicating that at least the layoff rate is higher in the United States. Information on the quit rate is less reliable, and the particular labor market inefficiencies responsible for the relatively high proportion of voluntary turnover incurring unemployment are also unclear.

3. *The Duration of Unemployment*

The evidence in the preceding sections indicates that international variations in the flows of new unemployment and new vacancies alone imply a relatively high UV relation and thus Phillips curve for the United States. It remains to discover whether the influence of the flow of new unemployment is reinforced by the average time spent between jobs in the sample countries. (Data limitations preclude study of the average duration of vacancies.) Here the distribution of unemployment by duration is important, for each of the countries complains of structural problems, and at times the relatively high unemployment rates in the United States

[21] Data on gross labor force flows in the United States are published for the early postwar period only. For 1949–52, we find

	1949	1950	1951	1952
Additions to labor force (LF) as a percent of LF	4.5	4.7	5.2	5.1
Unemployment rate:	5.9	5.3	3.6	3.1

Source: U.S. Bureau of the Census.

have led casual observers to infer that these problems are relatively severe in the United States. If this view were correct, one would expect to find a relatively large and cyclically insensitive amount of long duration unemployment in the United States, implying that bottlenecks will be reached relatively early in an expansion and that the gap between actual and desired (equilibrium) employment will be relatively large. This view can be tested by observing U_d, the rate of long duration unemployment (i.e., the number of people unemployed thirteen weeks or more as a proportion of the labor force, except in the United States where published data are for fifteen weeks and over), and by estimating its cyclical sensitivity.

During the postwar period, long duration unemployment as a proportion of total unemployment has varied from 12 to 32 percent in the United States, 25 to 40 percent in Great Britain, and 11 to 22 percent in Sweden. Over the same period U_d, the rate of long duration unemployment has ranged between .33 and 2.14 percent in the United States, .48 and 1.43 in Great Britain, and from .30 to .62 in Sweden.[22] The width of the range is dictated by the amplitude of cyclical fluctuations and the cyclical sensitivity of long-term unemployment, but the minimum levels of the long duration unemployment rate do not indicate that the United States has a relatively difficult structural problem. But given the different flows of new unemployment, the lowest American long duration unemployment rates—.33 in 1953, .37 in 1952, and .48 in 1951—occurred in years when the aggregate unemployment rates were twice as large as rates commonly experienced in Sweden and Great Britain.

The cyclical behavior may be studied by estimating the coefficients of the following equation:

$$(11)\quad U_d = a_0 + a_1 U_t + a_2 U_{t-1} + a_3 t + e$$

in which U_d is the rate of long duration unemployment, U is the aggregate unemployment rate, t is the time trend, and e is the error term. The cyclical sensitivity of the long duration unemployment rate will be reflected in a_1 and a_2, while a_3 will indicate whether there has been secular change in the long duration rate, apart from cyclical influences. Since the current rate of long duration unemployment is the result of past as well as current labor market conditions, the lagged unemployment rate can also be introduced. (Also, reduced form estimates can be computed from regressions of U_d on $(U-U_d)$ and t.)

The parameters of equation (11) were estimated from annual data for the United States and Great Britain and from quarterly data for Sweden (where the only comparable and consistent series provide only eight annual observations). For the United States and Great Britain, both the structural and reduced form equations were estimated, and the results are provided in Table 5. For Sweden, the use of quarterly data enabled a more precise isolation of the lagged response of long duration unemployment to changing labor market conditions. The results of several experiments indicated that a lag of one quarter was optimal. This equation, which includes the seasonal dummies $D1$, $D2$, and $D3$, appears as regression 28 in Table 5.

There are two findings of interest. The first is that the cyclical sensitivity in the long duration unemployment rate is *greatest* in the United States (see regressions 20, 24, and 28). This conclusion stands from both the direct and reduced form estimation of a_1. The estimate of a_1 for the United States computed from regression 22 is .45 (the direct estimate in regression 20 is .46), and the reduced form estimate for Great

[22] Data are from *Manpower Report of the President*, Ministry of Labour *Gazette*, and Statistiska Centralbyrån. All data adjusted to *U.S.* definitions by procedures described in Flanagan, Appendix A.

Britain is .36 (compared with the direct estimate of .41).

The regressions imply that with an aggregate unemployment rate of 4 percent in each country, the corresponding rates of long duration unemployment would be .76 in the United States, .94 in Sweden, and 1.27 in Great Britain. Therefore, the evidence favors the conclusion that the relatively high extreme rates of long duration unemployment which have been observed in the postwar United States are indicative of loose labor markets rather than of relatively severe structural problems.

Secondly, while there is no discernible time trend in the United States, evidence of a secular increase in the rate of long-term unemployment appears in the British and Swedish regressions. The coefficients on the time trend in the latter countries are measured very precisely, and are relatively insensitive to the structural or reduced form specification.

To summarize, in each of the three sample countries there are structural problems. The literature of economic policy in each country is replete with references to "the regional problem," inflexible wage structures, and skill bottlenecks when unemployment is high. However, the analysis indicates that structural unemployment (as measured by the rate of long duration unemployment) is not *relatively* severe in the United States, so that the American UV relation is neither relatively steep nor displaced relatively far from the origin because of structural problems. These general conclusions are supported by the data

for sectors of the *U.S.* labor force which are often viewed as important sources of structural unemployment as defined above.[23] For example, the share of the aged, nonwhites and blue-collar workers in long duration unemployment declined between 1961 and 1969 as the aggregate unemployment rate fell from 6.7 to 3.5 percent, whereas the share of white-collar and service workers increased. The share of teenagers did increase over this period to 18 percent of the long duration unemployed. However, most teenager unemployment was of shorter duration—almost one-third of all unemployment of less than five weeks occurred among members of this age group. Since most of this short-term unemployment is experienced by labor force entrants and re-entrants this group may have an important impact on the cyclical stability of the I_u statistic, although it is not evident at this time that this unemployment reflects normal allocative frictions.[24]

IV. Conclusion

The results reported in this paper confirm that the *U.S.* Phillips curve presents a less favorable tradeoff for monetary and fiscal policies than wage inflation-unemployment relations observed abroad. Neither the autonomous influence of institutions on wages nor the influence of expected price changes are important explanations of the *relative* position of the *U.S.* curve during the postwar period. Instead, the *U.S.* tradeoff reflects the fact that the United States exhibits the most incomplete adjustment of supply and demand in the labor market. Moreover, labor market maladjustment apparently increased, inducing an even poorer tradeoff, during 1967–70. However, the relatively poor adjustment is not due to relatively severe immobilities in the United States, but reflects a relatively high rate of separations and labor force entry along with the associated unemployment. The reasons for the relatively high gross turnover flows in the United States are as yet not well understood, and the traditional presumption that turnover is a by-product of allocational efficiency may be particularly qualified by more thorough analysis of racial differences in gross flows.

These findings have some implications for labor market policies, which have generally been designed to narrow the gap between the vacancy and unemployment rates by reducing the average duration of unemployment or vacancies. To the extent that these programs are successful, they will shift a properly measured Phillips curve. However, in pursuing these programs, it should be recognized that they do not generally treat the main source of observed international differences in Phillips curves—the factors responsible for the high incidence of unemployment and vacancies in the United States at every rate of excess demand—except to the extent that they reduce the percentage of quits, layoffs, and labor force entrants which incur unemployment.

[23] Data in this paragraph are from *Manpower Report of the President*, pp. 225–28.

Required Disclosure and the Stock Market: An Evaluation of the Securities Exchange Act of 1934

By GEORGE J. BENSTON*

The Securities Exchange Act of 1934 was one of the earliest and, some believe, one of the most successful laws enacted by the New Deal. The stock market crash in 1929 and the Great Depression provided the impetus for reform of the stock markets in the belief that weaknesses of the institutions and ineptitude and/or chicanery among brokers and bankers were partially responsible for the losses incurred by stockholders. Although many critics, reformers and congressmen wanted Congress to enact "blue skies" legislation that would require all securities sold and traded to be approved by the federal government, President Franklin Roosevelt preferred the concept of "disclosure" (see Francis Wheat (1967)). Rather than having the government approve or disapprove securities, corporations whose securities are publicly sold and traded are required to disclose a large amount of predominantly financial information to the Securities and Exchange Commission (*SEC*) who make these data available to the public. Indeed, the Securities Exchange Act is described in its title and usually referred to as a "disclosure statute."

Although the financial community generally opposed this legislation and the preceding Securities Act of 1933,[1] most brokers, investors and government officials probably would find it difficult to conceive of the successful operation of the stock markets without the Securities Acts. Yet the economic rationale for the regulation of the securities markets was not examined carefully before the legislation was passed (which is not surprising, given turbulent times) nor has it been since,[2] even though the Securities Act of 1934 was extended in 1964 to include most corporations whose stock is publicly owned. Such an examination of one important part of the law—the financial disclosure requirements—is presented here. This analysis is particularly timely because the *SEC* appears to be shifting its emphasis towards increasing the disclosure requirements of almost all corporations whose stock is traded in the markets.[3]

* Professor, Graduate School of Management and Center for Research in Government Policy and Business, University of Rochester. Thanks are due to Robert Hagerman and Stanley Engerman for their criticisms, some of which I agree with.

[1] A recent history by Ralph DeBedts reviews these events uncritically.

[2] George Stigler (1964a, b) and Irwin Friend and Edward Herman provide the first quantitative analysis of the Securities Act of 1933 of which I am aware. The only other analyses are in two papers which I published in 1969.

[3] A rather detailed "Report and Recommendations to the Securities and Exchange Commission" from the Disclosure Policy Study headed by Wheat recommends:

> . . . that for the future, greater attention be paid to those continuing disclosures which benefit the trading markets in securities. Prior to 1964 the continuing disclosure reached only those issues whose securities were listed on exchanges and those which had voluntarily registered securities under the '33 Act. Full exercise of that authority might have deterred listing. This is no longer the case, and a serious impediment to progress in disclosure policy has been removed. [Wheat Report, p. 11]

I. The Disclosure Requirements of the Securities Exchange Act of 1934

The '34 Act requires that a corporation whose stock is traded on a registered stock exchange or who registered a stock issue:

a) file detailed balance sheets, income statements, and supporting substatements (form 10K) within 120 days after the close of its fiscal year;

b) file a much less detailed semiannual report (form 9K) within 45 days after the first half of the fiscal year;

c) file a "current report" (form 8K) 10 days after the end of any month in which certain "significant" events occurred (such as a change of control of the corporation, material legal proceedings undertaken, material change of securities outstanding, and revaluation of assets).

In 1964, the disclosure requirements were extended to almost all corporations with at least 500 stockholders or $1 million in assets. (Exceptions are regulated companies whose statements were prescribed, such as banks and insurance companies). Thus, all but the smallest corporations now are covered by the Act.

Section 13(b) of the '34 Act (and section 19(a) of the '33 Act) gives the *SEC* the power to prescribe the form and content of the financial statements filed under the Act. In general, the *SEC* has followed generally accepted accounting procedures, although it has influenced these procedures by insisting that assets not be revalued upward, goodwill be amortized rapidly, and other "conservative" biases be reinforced. In this regard, the *SEC* has not followed the "disclosure rather than approval" philosophy of the Securities Exchange Act. This policy was established by Accounting Series Release No. 4 in 1938, which states that

> . . . where financial statements filed . . . are prepared in accordance with accounting principles for which there is no substantial authoritative support, such financial statements will be presumed to be misleading or inaccurate *despite disclosures* contained in the certificate of the accountant or in footnotes to the statements provided the matters involved are material. (italics added.)

Whether disclosure, as defined and required by the *SEC*, has been meaningful and beneficial, is the question asked here—not whether disclosure, as such, is good or bad.[4]

II. The Rationale Underlying the Legislation

It would seem that any argument against disclosure is equivalent to an argument for secrecy. But such is not the case. Prior to the passage of the Securities Exchange Act, corporations could disclose what they wished to their current and potential stockholders and, if they were listed on the New York Stock Exchange (*NYSE*), American, Chicago (Midwest), or other regional exchanges, had to submit balance sheets and income statements to the Exchange. For the year ended December 31, 1933, all *NYSE* corporations were audited by CPA firms, all listed current assets and liabilities in their balance sheets, 62 percent gave their sales, 54 percent the cost of goods sold, and 93 percent disclosed the amount of depreciation expense. These percentages had been increasing fairly steadily prior to 1933, although there was little change after 1928. (See Benston (1969b), p. 519.) One could argue (as did the *NYSE*), that the legislation was not needed.

One could also argue that the disclosure policy followed by corporations in the absence of legislation is in the best interests

[4] The possible detremental effect of the *SEC*'s definition of disclosure on the development of improved and innovative accounting procedure has been argued elsewhere (Benston, 1969b). While the issue is important to the question of the efficient operation of securities market, it is not emphasized in this paper.

of their stockholders. If management believed that the marginal revenue to the stockholders as a group from disclosure would exceed the marginal cost of preparing and supplying the information, they would disclose their financial and other data. The marginal revenue might include the savings to stockholders of not having to gather the data privately, the reduced cost of capital to the firm if prospective stockholders' uncertainty about the firm were reduced, improvement in the marketability of the firms' shares if investors desired financial information, etc. The marginal costs of disclosure might include the cost of preparing and distributing the statements, the costs incurred in informing competitors, suppliers, customers, and government officials, and the cost of misinforming stockholders when accounting statements report economic events incorrectly or inadequately (as when all research and development and advertising expenditures are charged to expense currently).

However, management might not issue financial statements (or might issue incomplete statements) if they underestimate the value of these statements to their current or potential investors, mismanage the corporation, intend to defraud investors, or if there are positive externalities in the efficient allocation of resources when all (or most) companies disclose financial data. Thus, one cannot immediately dismiss the argument that there is need for required disclosure solely by reference to the invisible hand of the market. Rather the question must be examined with respect to the rationale upon which the Securities Exchange Act of 1934 is based.

Underlying the disclosure requirements of the '34 Act is the belief that required disclosure of financial data is necessary for the fair and efficient operation of capital markets. The *SEC*'s 1969 Wheat Report (and most other writings on the subject) view disclosure as necessary to 1) prevent financial manipulation and 2) provide investors and speculators with enough information to enable them to arrive at their own rational decisions. (Wheat Report, p. 10.)[5] Perhaps even more important is the concept of "fairness," the belief that all investors, big and small, insiders and outsiders, should have equal access to relevant information. Whether these objectives can be achieved, a priori, by disclosure of financial data, and if they can, whether or not the evidence supports or rejects the hypothesis that they were, is considered in the balance of the paper. To facilitate the presentation of the material, fraud and manipulation is discussed first in Section III, followed by an empirical analysis of information and investors' decisions in Section IV, and the effects of the '34 Act on traded securities in Section V, on losses by stockholders in Section VI, and on investors' confidence in the market in Section VII.

III. Fraud and Manipulation

Fraud and manipulation may be of two different types with respect to disclosure. Published statements may contain false or misleading data or desired data may not be published at all but may be released in the form of news stories, rumors, etc., to manipulate the public's expectations and so affect stock prices. These are discussed in turn.

It is very difficult to determine whether the '34 Act prevented the publication of

[5] Also mentioned is ". . . the belief that appropriate publicity tends to deter questionable practices and to elevate standards of business conduct" (p. 10). These goals are inherently nonoperational, except as they refer to the prevention of fraud and manipulation, which is discussed below, or perhaps to insider stock dealings, which is not affected by the disclosure of financial data and hence is outside the scope of this paper. However, see Henry Manne for one view contrary to the *SEC*'s position.

fraudulent or misleading financial statements or even whether much fraud existed to any greater extent before or after the passage of the Act. In a situation of personal fraud by self-dealing or simple defalcation, required disclosure is of little value. Certified Public Accountants insist they they do not audit explicitly for fraud nor does the *SEC* ask them to do this, although I believe a good case could be made for this requirement. With respect to fraudulently prepared financial statements, I have reviewed such evidence as exists in another article (Benston (1969a), pp. 51–55). A search of the available literature, including the Senate and House hearings on the proposed securities legislation, fails to reveal much evidence of fraud in the preparation or dissemination of financial statements prior to 1934. For example, Wiley Rich, the author of a comprehensive survey of the legal responsibilities of accountants, states that "An extensive search has revealed not a single American case in which a public accountant has been held liable in a crime for fraud" (p. 100). It appears that the feeling in the early 1930's that published accounting statements were fraudulent or misleading was based on the "exposés" of William Ripley and others of the behavior of some large corporations at the turn of the century. Further, the recent BarChris, Yale Transport, Green Department Store, Continental Vending, and other cases show that fraud in financial statements, while relatively rare, has not been banished from the land.

The lack of evidence on fraudulent financial statements does not imply that published financial statements were or were not misleading. Prior to the passage of the Securities Act, it was very difficult for third parties, such as prospective stockholders, to sue accounting firms for negligently prepared financial statements. The courts held, under the rule of privity, that these reports were prepared for management only. (See Landell v. Lybrand.)

However, accountants were (and still are) liable for fraud " . . . if their audit has been so negligent as to justify a finding that they had no genuine belief in its adequacy for this again is fraud." (See Ultramares Corp. v. Touche, Niven and Co. N.Y. p. 185, N.E. p. 488.) The Securities Act changed accountants' liability dramatically, and now an investor may sue an accountant if, having relied on false or misleading statements, he "shall have purchased or sold a security at a price which was affected by such statement" (Section 18). It is important to note that the accountant must prove that the investor's loss was not a consequence of the financial statements rather than that the investor prove that he actually was misled by or even saw the statements.

In contrast to the lawmakers' expectations, an important consequence of this change in the law and of the *SEC*'s administration of the Acts appears to be that financial statements are more misleading than they were. The considerable liability of accountants under Section 18 has contributed to accountants following conservative, often worthless practice, since it is difficult to sue them successfully for preparing misleading statements if they follow traditional procedures. In addition, the *SEC* has insisted on historically based accounting, discouraging price level and other revaluation of assets and liabilities, refusing to permit publication of sales and income projections and other valuable economic data, etc. Thus published financial statements are more misleading than they otherwise might have been. Although accountants might not have made much progress in reporting the economic position and progress of corporations had there been no Securities Act, there is no empirical or a priori basis for an assertion that the '34 Act has had a net positive

effect on the publication of fraudulent or misleading financial statements.

While there is little direct evidence that corporate managers issued fraudulent financial statements, they may have refused to disclose information to create a climate in which they could manipulate stock prices by means of "pools" and "bear raids." At least such is the opinion of the *SEC*. In their booklet, *A 25 Year Summary of the Activities of the Securities and Exchange Commission, 1934–1959*, they say these practices

> . . . resulted in a situation in which no one could be sure that market prices for securities bore any reasonable relation to intrinsic values or reflected the impersonal forces of supply and demand. In fact, the investigation record demonstrated that during 1929 the prices of over 100 stocks on the New York Stock Exchange were subject to manipulation by massive pool operations. One of the principal contributing factors to the success of the manipulator was the inability of investors and their advisers to obtain reliable financial and other information upon which to evaluate securities. . . . [pp. xv–xvi]

To test this assertion, the financial statements (as published in *Moody's Investors Services*) of those over 100 corporations whose securities were subject to pools, as revealed by the Senate Committee on Banking and Currency, were examined for years before, during, and after the pools. Table 1 gives the percentage that disclosed such important information as sales and cost of goods sold. (All except 4 corporations included in the 1929 pools and 2 included in the 1930 pools had otherwise complete balance sheets and income statements published in *Moody's*.) The percentages with respect to sales were almost the same as those found for all companies listed on the New York Stock Exchange and a little lower with respect to cost of goods sold. Thus, while "pools" and "bear raids" may or may not have been unfair to investors, it is clear that their operations (successful or not) owed little to the nondisclosure of accounting data.

IV. Information and Rational Decisions of Investors and Speculators

The second rationale for the disclosure requirements is to allow "investors [to] make a realistic appraisal of the merits of securities and thus exercise an informed judgment in determining whether to pur-

Table 1—Disclosure of Financial Data by Corporations Whose Securities were Subject to Pools

		Percentage Disclosing[a]	
Pool Year	Statement Year	Sales	Cost of Goods Sold
1929 Pools	1927	58	47
(103 corporations)[b]	1928	58	48

[a] Corporations whose statements were not in *Moody's* (4 of the 1929 pools and 2 of the 1930 pools) are included as "nondisclosure."

[b] Number of securities = 105; 2 securities of two corporations were listed

[c] Number of securities = 31; 2 securities of one corporation were listed

[d] Number of securities = 13; 2 securities of one corporation were listed

chase them" (Securities Exchange Commission, 1967, p. 1). This rationale is based on a belief that the data required by the *SEC* are "information." That is, the financial statements must provide data about a corporation that affect investors' expectations about its future prospects and relative riskiness and that were not previously known, such that the information was completely discounted and impounded in the market price of the securities before the time of disclosure.

There is serious question whether the financial data approved by the *SEC* can provide the investor with information. The *SEC* does not allow current market valuation of assets, estimates of future sales or projection of the effects of discoveries, favorable regulatory rulings, public acceptance of new products and other economic events. Additionally, the present value of many important occurrences such as management changes, styling, advertising campaigns and other marketing strategies, changes in the competitive environment, and the like cannot be estimated very well even if the *SEC* allowed accountants or others to publish their efforts. While this information need not come to the public through the financial statements, the *SEC*s requirement that these statements be prepared in a specified form implies that they include some relevant quantitative financial information.

But even if financial statements do contain information that is of value to investors, the data may not be made available to the public before insiders (including bookkeepers, secretaries, accountants, typists, and printers) see and take advantage of them. In requiring the filing of financial statements, the *SEC* is caught in a choice between speed and accuracy (in the sense of reporting to the letter of the formal and informal regulations), a choice which is resolved in favor of accuracy. As is noted above, the annual reports (10K) need not be filed with the *SEC* until 120 days after the close of a corporation's fiscal year. Whether the statements that have been filed are meaningful to investors and sufficiently timely to be of value is, of course, an empirical question, to which I now turn.

A. *The Information Content of Published Financial Data—Financial Statements and Stock Prices*

If the *SEC*'s disclosure requirements are meaningful, the statements they require should contain information, and thus investors' expectations about a corporation's earnings and prospects, riskiness, relationship to other firms, etc., should be affected by the information. Since numerous studies show that the market adjusts rapidly to new information,[6] the effect, if any, of previously unexpected data published in the financial reports of a corporation (j) should be reflected in changes in its stock prices (ΔP_{jt}) in the period t when these unexpected financial data (F^*_{jt}) become publicly available. Other factors also may occur during the same period and must be accounted for. Principal among these are changes in general market conditions (ΔM_t), changes in expected dividend payments (which often are announced at the same time that earnings data are announced) (ΔD_{jt}), and changes specific to the corporation's industry (ΔI_{kt}). In summary,

$$(1) \quad \Delta P_{jt} = f(F^*_{jt}, \Delta M_t, \Delta D_{jt}, \Delta I_{kt}, U_{jt})$$

where U_{jt} are other unspecified factors. This model was specified and tested, and the results were reported in a paper I published in 1967. They are summarized very briefly here. The specified model whose description follows was used for these tests, used in another study reviewed be-

[6] See Eugene Fama for a summary and review.

low (Ray Ball and Phillip Brown), and in further tests described below in Section V.

A two-stage estimating procedure was used that is based on a "market model" originally suggested by Markowitz and first applied in a context similar to the present study by Eugene Fama et al.

$$\tilde{r}_{jt} = \alpha_j + \beta_j r_{Mt} + \tilde{u}_{jt} \tag{2}$$

where $\tilde{r}_{jt}$ is the rate of return for security j for month t (defined as $ln((P_{jt}+D_{jt})/P_{jt-1})$ where P_{jt} is adjusted for stock dividends and splits and D_{jt} is dividend payments declared); r_{Mt} is a similarly measured rate of return on a market index M; α_j and β_j are parameters that can vary from security to security; and $\tilde{u}_{jt}$ is a random disturbance.[7] Tests applied by Fama et al., and Marshall Blume (1968, 1970) indicate that equation (2) ". . . is well specified as a linear regression model in that (i) the estimated parameters α_j and β_j remain fairly constant over long periods of time [e.g., the entire post-World War II period in the case of Blume], (ii) r_{Mt} and the estimated $\hat{u}_{jt}$ are close to serially independent, and (iii) the $\hat{u}_{jt}$ seem to be independent of r_{Mt}" (Fama, p. 403). The $E(\hat{u}_{jt}|F^*_{jt})$ may not$=0$. This is what was tested.

Equation (2) was applied in my 1967 paper to a sample of 483 companies traded on the New York Stock Exchange in 1964 (the latest year data were available at the time of the study). These included almost all *NYSE* traded companies from whom annual and quarterly financial data were available on the Compustat tapes. The statistics $\hat{\alpha}_j$ and $\hat{\beta}_j$ were computed from data that excluded months when the financial statements were made public. These statistics were then "plugged" into equation (2a) to compute the residuals, $\hat{u}_{jt}$, for the months when the financial data were published:

$$\tilde{r}_{jt} - \hat{\alpha}_j - \hat{\beta}_j r_{Mt} = \hat{u}_{jt} \tag{2a}$$

The $\hat{u}_{jt}$ computed with equation (2a) were regressed on estimated unexpected financial data, unexpected dividends, and variables that accounted for industry effects.

An expectation model had to be specified in order to estimate the unexpected financial data (F^*_{jt}). Since the *SEC*'s regulations require disclosure of accounting statements for prior periods as well as the present period,[8] expected financial data were taken to be a function of previously published data. Three averages of past data (a weighted average with geometrically declining weights determined by a variant of the Koyck transformation, and simple averages of three and five years' data) and a naive model (previous year's data) were used. Unexpected financial data F^*_{jt}, then, is measured by the difference between the reported and the expected data. Although the *SEC* did not require companies to report their quarterly data until recently, such data were required by the *NYSE*. Since investors' expectations would be affected by these reports, their effect is estimated by including third quarter financial data in the regressions in forms analogous to those used for the annual data.[9]

Since it is not clear which specific financial data investors use, the financial variables were defined alternatively as sales, cash flow net income, current operating income, and net income after extraor-

[7] Fama shows that this model is consistent with the Sharpe-Markowitz expected return model.

[8] The *SEC* requires that companies who float a stock issue under the provisions of the Securities Act of 1933 publish at least five years of comparative data, three of which must be certified by an independent certified public accountant.

[9] There is some possibility that these third quarter data could be collinear with the annual data, which might reduce the significance of the measured coefficients. I am indebted to Ross Watts for pointing out this possible error.

dinary gains and losses. Thus sixteen regressions were computed for the month when the financial data were sent to the *SEC* and stockholders (four expectations models and four definitions of income).

The regressions reveal that, except for the sales definition of financial data, none of the financial data variables in any of the expectations forms has a greater than minimal economic relationship to changes in stock prices, although the coefficients estimated are statistically significant. On the average, a 100 percent unexpected increase (or decrease) in the rate of change of income is associated with a 2 percent increase (or decrease) in the rate of change of stock prices in the month of announcement. Similar regressions were computed for the month when earnings were announced (which usually is a month before the *SEC* receives them), and similar results were found. The findings are not very dependent on the form of the expectations model used, although the naive model, where last year's rate of change is expected this year (a sort of "no-expectations" model), performed the best. This finding is contrary to the *SEC*'s requirement that companies provide comparative data for several past years. Thus, I conclude that this evidence is not consistent with the underlying assumption of the legislation, that the financial data made public are timely or relevant, on average.

Corroborative findings are reported by Ball and Brown, whose study used a variant of the model described above in equation (2). Their sample consists of 261 firms who reported on an annual basis. For most of these firms, data were available in the period 1946 through 1968 on the Compustat tapes. Ball and Brown considered each firm's year as an independent observation. They separated the data into two samples, one consisting of years in which income increased and the other of years in which income decreased unexpectedly, as determined from an expectation model in which a firm's expected income is a function of the income reported by the other firms. However, they did not account for dividend changes or for the information content of quarterly reports. Ball and Brown found that cumulatively, over a year, firms that show greater (or lesser) than expected income changes averaged greater (or lesser) than normal stock price returns. However, they calculate that ". . . of the value of information contained in reported income no more than 10 to 15 percent . . . has not been anticipated by the month of the [preliminary] report . . ." and compute that the marginal monthly rate of return of buying or selling short a portfolio of stock based on the information contained in the preliminary report is less than 1 percent (pp. 175–76). By the time of the final (*SEC*-required) report, there is almost no information that has not already been impounded in the price of the stock.

Another study of interest was made by William Beaver, who measured the volume of trading in the weeks before and after the announcement of preliminary earnings. He analyzed weekly price and volume for a sample of 143 firms (those included on the Compustat tape, traded on the *NYSE*, with other than December 31 fiscal years, with no dividends announced in the same week as the announcement, no stock splits in the quarters around that date, and with relatively few other "announcements"). A model similar to that given in equation (2) was used to abstract from market effects. Beaver found that the variance, average volume, and residual positive or negative return are much greater in the week that the preliminary reports are announced (without regard to the sign or magnitude of the earnings) than in the previous or following eight weeks. Further, the greater than normal activity appears to continue for about two to

three weeks after the announcement date, but with a considerably smaller magnitude. Contrary to the other studies, Beaver's results seem to indicate that financial statements do contain information or are at least used in some way. One interpretation is that investors use the announcements of preliminary earnings to switch their portfolios. Another is that brokers use the earnings reports as an excuse for "churning." A third explanation, one consistent with the findings of Robert Hagerman on the effect of requiring commercial banks to report earnings to the public in forms specified by regulatory agencies, is that while financial statements, as such, provide information, required reporting adds nothing. (Recall that all *NYSE* companies published some form of statement before passage of the '34 Act.)

One other study has been published that considers directly the usefulness of published annual financial statements in purchasing securities. Richard McEnally tested the value of using low price/earnings (P/E) ratios to choose portfolios of stocks. He used a randomly selected sample of 100 calendar-year stocks from which five portfolios of 20 stocks each were chosen for each of five years, 1961–65. High or low P/E ratios were the basis for forming portfolios. The stocks are assumed to be purchased on April 1 and held for a year. When the earnings used in the P/E ratio were those of the previous year (E_{t-1}), the portfolio with the lowest P/E_{t-1} outperformed the others slightly in terms of mean return, there being little difference among the other four portfolios.[10] McEnally then used the ratio of price to earnings of the year in which stocks were purchased, P/E_t (which assumes perfect forecast of the year's earnings in April), to choose portfolios. Except for the little difference between the third and fourth groups, the portfolios so chosen provided consistently higher holding period returns according to the P/E criterion. Since market participants do not have perfect knowledge of the year's earnings, McEnally used the earnings forecasts of the three most popular advisory services of the P/E ratios. The results were almost the same as those reported for published earnings. Thus the research is consistent with Ball and Brown's study in that financial statement data seems to reflect the economic situation of corporations but either are completely discounted by the market before they are published or do not predict the economic future. In either case, the data are not useful to investors at the time the *SEC* requires disclosure.

B. *Returns to Sophisticated Users of Financial Data*

It may be that the studies cited above approach a complicated problem in too simple a way. It often is claimed that the detailed reports required by the *SEC* are more useful to trained analysts than to the ordinary stockholder. The analyst then passes on his information to his clients or, in any event, trades on the information, thereby bringing its effects to the market. No doubt information about firms does get to the market. But does it get there by means of the financial reports required by the *SEC*?

One way to answer these questions is to examine whether well-trained analysts out-perform the market. I am aware of two studies that test directly the ability of security analysts to use published financial data. John G. Cragg and Burton Malkiel recorded predictions made by five

[10] The geometric mean return for the lowest P/E_{t-1} portfolio is 1.20 compared to the average of all portfolios of 1.15. No significance tests were made. However, McEnally reports that "Simple correlation coefficients between P_t/E_{t-1} and the next year's holding period return for these five holding periods . . . cast doubt on the validity of any relationship" (p. 30).

investment firms of the earnings of 185 corporations whose stock is widely held. In particular, they compared the earnings' growth rate forecast by the analysts with the actual growth rates. They report that "... the remarkable conclusion of the present study is that the careful estimates of security analysts participating in our survey, the bases of which are not limited to public information, perform little better than the past growth rates" [the naive predictor, that the future will be like the past] (p. 83). The second study, by Lyn Pankoff and Robert Virgil, was a controlled, laboratory study. They allowed security analysts to "buy" financial statements of companies in whose stock they can invest. The data are actual data and the stock prices are those that actually prevailed for the stocks whose identity they disguised. While their study is not yet complete, Pankoff and Virgil found that analysts who use financial data (or any other data) do not do as well as they could have had they followed a "naive" buy and hold strategy.

Several indirect tests of the ability of trained analysts to use financial data publicly can be derived from studies of the performance of mutual funds and research departments of brokerage houses. F. E. Brown and Douglas Vickers, William Sharpe, and Michael Jensen studied the performance of mutual funds compared to that of random selections of securities with similar risk characteristics. They used different techniques and all came to the same conclusion. Mutual funds do not earn for their investors a higher rate of return than would have been earned had the investors held a similarly diversified market portfolio, gross of research costs. Nor is the record of the research departments of brokerage houses any better. A study by R. E. Diefenback of the market performance of stocks whose purchase or sale was recommended by twenty-four institutional research services found that their recommendations, if followed, would have yielded returns equivalent to those earned by investments in the Standard and Poor's (S and P) 425 Index. Thus, even mutual fund and brokerage house research department analysts do not benefit from detailed analysis of *SEC* reports, among other data.

Even though the evidence reviewed does indicate that the financial reports required by the *SEC*, when made available, have almost no information content, this does not prove that the required disclosure is not valuable to investors. One might argue that the statements provide a confirmation of data previously released. Because investors know that a corporation's sales, operating expenses, extraordinary gains and losses, assets and liabilities will be reported, they may have some assurance that the preliminary reports, press releases, etc., are not prevarications. Thus when the financial statements are made public the data they contain are fully anticipated. But had it not been for the *SEC*'s disclosure requirements, such a state of affairs might not exist. It is to this consideration that I turn next.

V. An Empirical Analysis of the Effect of the '34 Act on *NYSE* Securities

When the Securities Exchange Act was enacted in June 1934, the United States was in the midst of the Great Depression. Hence, it is difficult to separate the effect of the legislation on the stock market from other economic events, and the effect of the disclosure requirements of the Act from its other provisions. In addition, it is necessary to determine when the legislation affected the stock market, since it might have been anticipated such that, when passed, its impact already had been discounted.

Fortunately, the data and the particular legislative history of the '34 Act allow an

unusual opportunity to test the effect of legislation. Hearings on the '34 Act did not begin until February 1934, nor was there much belief before this date by most observers that such legislation would be enacted (see Sobel). Prior to this time, it was not considered part of the President's legislative "package." Nevertheless, the bill was signed by President Roosevelt in June 1934 and took effect that year, although full compliance did not occur within the year. Therefore, I have considered the period of adjustment to include February 1934 through June 1935. Thus there is a relatively short and distinct period over which the effect of the legislation may be measured.

The effect of the disclosure provisions of the Act may be tested by examining its differential effect on the securities of corporations that were and were not affected by the legislation. At the time of the passage of the Securities Exchange Act of 1934, about 70 percent of stock exchange transactions were made on the *NYSE*, 13 percent on the American (Curb) Exchange, 1.6 percent on the Chicago (Midwest) Stock Exchange, and the balance on nineteen other regional exchanges. The three principal exchanges, at least (the others didn't reply to my inquiries), had similar rules that required listed companies to send certified income statements and balance sheets to stockholders in advance of the annual meeting. The principal reporting requirement imposed by the '34 Act, in addition to the filing of detailed forms, was the required disclosure of sales. Of the 508 corporations whose stock was traded on the *NYSE* in 1934, 193 (38 percent) did not disclose their sales.[11] Since sales are considered very important information by analysts, and the study reported above (Benston (1968)) found sales the only relatively important accounting number, these corporations are considered as those most likely to be affected by the disclosure requirements of the '34 Act.[12]

Thus two samples of *NYSE* corporations can be distinguished: the 314 (62 percent) "disclosure" corporations and 193 (38 percent) "nondisclosure" corporations (with respect to sales). These data allow a fairly comprehensive test of the law, since the '34 Act applied (until 1965) only to corporations whose stock is traded on registered exchanges, and most of these corporations were listed on the *NYSE* in 1934. If disclosure of the sales data required by the '34 Act were meaningful to investors, these effects should be observed in the market returns of the securities affected in the period after the law was effective. As was discussed above in greater detail, if the data disclosed are information, investors would alter their previous estimates of the relative value and/or riskiness of the firms.

The model given by equation (2) above can be used to measure these effects. The $\hat{u}_{jt}$ measure the returns on a security after the effect of changes in the return for the market as a whole is accounted for. A change in the $\hat{u}_{jt}$ represents a revaluation of the present value of future returns from a security. As such, it provides a valuable measure of the information content of mandated disclosure.

The $\hat{\beta}_j$ provide a measure of the relative systematic portfolio risk of a security, its covariance with the market relative to the market's variance.[13] As such the $\hat{\beta}_j$ might be affected if the data disclosed in the financial statements provide information about the risk class of a company and the

[11] Fifty-four percent did not report "cost of goods sold," almost all of whom also did not report sales. (See Table I in Benston (1969b).)

[12] The analysis also was carried out for the corporations that did and did not disclose cost of goods sold, with similar results to those reported.

[13] See Fama, pp. 401–04, for a more complete exposition of this concept.

relationship of its economic value to changes in the economy (as reflected by the market).

The variance of returns from a stock may be stated as:[14]

$$(3) \qquad \sigma^2(r_j) = \beta_j^2\sigma^2(r_M) + \sigma^2(u_j)$$

where the variables are as defined for equation (2) above. The variance of returns on a security, j, can be reduced by reducing the variance of the market, $\sigma^2(r_M)$, the sensitivity of the security to the market, β_j, and/or the residual variance, $\sigma^2(u_j)$. Fisher and Lorie's study shows that the dispersion of the market index is higher for the immediate post-'34 Act period than it was in the years before 1932. It is not until 1945 that it is of a lower magnitude than the late 1920's. A reduction in the β_j, though, would reduce the variance in stock's returns. While a reduction in the variance of the residuals of a stock, $\sigma^2(u_j)$, also reduces the variance, it should be noted that investors can reduce or eliminate this "risk" by holding a portfolio of securities. Let

$$r_p = \sum_{j=1}^{n} \frac{1}{n} r_j$$

be the returns on a portfolio of securities with an equal dollar investment in each security. The variance of the returns on such a portfolio is given by

$$(4) \qquad \sigma^2(r_p) = \left(\sum_{j=1}^{n} \frac{1}{n}\beta_j\right)^2 \sigma^2(r_M) + \sum_{j=1}^{n} \frac{1}{n^2}\sigma^2(u_j) = \bar{\beta}^2\sigma^2(r_M) + \frac{1}{n}\overline{\sigma^2(u)}$$

assuming that $\mathrm{cov}(u_i, u_j)=0$ for $i \neq j$. As n, the number of stocks in the portfolio increases, the residual variance of the portfolio goes to zero (as long as the $\sigma^2(u_j)$ are bounded from above). Nevertheless, the legislators and many economists believe it desirable to reduce the riskiness of individual stocks, since "small investors" cannot purchase enough different securities for efficient diversification.[15]

Thus, three statistics derived from equation (2) are of interest: $\hat{u}_{jt}$; $\hat{\beta}_j$; and $\sigma^2(\hat{u}_{jt})$. Equation (2) was computed for each *NYSE* traded security on monthly data for the period January 1926 through January 1934 (pre-*SEC* period) and July 1935 through November 1941 inclusive (post-*SEC* period). January 1926 was taken as the initial month because this is the first month for which data are available on the Center for Research on Security Prices (*CRSP*) tape of *NYSE* monthly security prices.[16] November 1941 was taken as the last month because it allowed for the longest post-*SEC* period that did not include the next major dislocation—World War II. There are 98 months in the pre-*SEC* period and 90 in the post-*SEC* period. To allow for a sufficient number of observations for the regressions, securities that were traded for less than 10 months in each time period were excluded.[17] This left 466 companies, of whom 290 are disclosure corporations (62 percent) and 176 nondisclosure corporations (38 percent).[18]

Five hypotheses about the effectiveness of required disclosure can be tested with

[14] I am indebted to Michael Jensen for clarifying my thinking on this issue and for the equations presented.

[15] While small investors can purchase mutual funds to obtain diversification, this alternative may not be considered sufficient or even desirable by legislators.

[16] The Center is at the University of Chicago. The tape presently is administered by the Standard Statistics Corporation.

[17] A study of the disclosure practices of corporations who left the *NYSE* before February 1934, and hence were excluded from the analysis, is presented below.

[18] Since the percentages of disclosure and nondisclosure corporations are the same, this procedure does not appear to have introduced any obvious bias.

observations of the $\hat{\beta}_j$ and $\sigma^2(\hat{u}_{jt})$ for the periods before and after disclosure and of the $\hat{u}_{jt}$ for the adjustment period following immediately after required disclosure.

1) Managers avoided disclosure to hide their poor performance:

If the managers did not publish financial data because they wanted to hide their poor performance from their stockholders, the $\hat{u}_{jt}$ of the nondisclosure companies compared to the disclosure companies would be negative since investors would revalue downward the returns to the securities. Similarly, such managers might not disclose financial data to mislead investors about the relative riskiness of the firm, in the hope that stockholders might be willing to hold stock having a lower rate of return if they believed the firm to be less risky than it really was. In this event, disclosure would result in higher $\hat{\beta}_j$ if the market (portfolio) risk of the nondisclosure firms was underestimated and greater $s^2(\hat{u}_{jt})$ if the individual, diversifiable security risk was underestimated and not diversified away.

2) Managers did not disclose because they did not realize the value of the information to investors:

If required disclosure provided investors with valuable information, the $\hat{u}_{jt}$ would change, and the $\hat{\beta}_j$ and $\sigma^2(\hat{u}_{jt})$ might change. However, the direction of the changes cannot be predicted.

3) Required disclosure imposes a cost on corporations without compensating benefits to stockholders:

If managers were disclosing adequately before the legislation was passed (the marginal cost of disclosure equaled its marginal benefits), investors might view disclosure as a net cost imposed on the firm. (Included in this cost is the value of the information to competitors.) In this event, the $\hat{u}_{jt}$ would decrease (as in hypothesis 1)), but there is no reason to believe that the $\hat{\beta}_j$ and $\sigma^2(\hat{u}_{jt})$ would be affected.

4) Required disclosure results in benefits to the market as a whole because investors would prefer stocks on registered exchanges to alternative investments, such as over-the-counter stocks or real estate. However, some costs are imposed on those firms that would not otherwise have disclosed:

If this hypothesis holds, the $\hat{\beta}_j$ and $\sigma^2(\hat{u}_{jt})$ should not be affected, the $\hat{u}_{jt}$ of the firms that were required to disclose might decrease and the $\hat{u}_{jt}$ of firms that were not so affected might increase, as investment in equities traded on the stock exchanges became relatively more attractive to investors. Thus the difference in the $\hat{u}_{jt}$ between disclosure and nondisclosure firms should be positive.

5) Required disclosure did not impose sufficient costs or benefits to be measured:

Should the "null" hypothesis obtain, there would be little change in the $\hat{u}_{jt}$, $\hat{\beta}_{jt}$, or $\sigma^2(\hat{u}_{jt})$. Of course there could be costs to firms not traded at the time (such as the cost of newly registering with the *SEC*) or costs or benefits too small to be measured by the model.

Tests on the $\hat{\beta}_j$ are discussed first because, if the $\hat{\beta}_j$ are stable between periods, the $\hat{u}_{jt}$ can be computed more efficiently by using data from the entire data set, excluding the adjustment periods.

Table 2 gives the mean differences of the $\hat{\beta}_j$ computed for the pre- and post-*SEC* periods, in both algebraic and absolute terms.[19] Distributions of the $\hat{\beta}_j$ show them

[19] The means (and standard errors of the means) of the $\hat{\beta}_j$ in the pre-*SEC* period is .9968 (.0202) for the disclosure corporations and .9854 (.0312) for the nondisclosure group. In the post-*SEC* period, these statistics

to be approximately normally distributed, so the standard errors of the means given in Table 2 can serve as valid summary statistics.[20] Since the stability of the $\hat{\beta}_j$ are dependent, in part, on the number of observations used to compute them, the average number and standard deviations of the underlying observations also are given in Table 2. These data do not indicate any bias between the groups from this source. The algebraic differences between periods for both groups are positive, but hardly greater than zero and almost of the same magnitude and dispersion for the disclosure and nondisclosure groups. The absolute differences are presented because several of the hypotheses do not specify a change in the $\hat{\beta}_j$ of any particular sign, and the algebraic means could mask significant changes. Of course, the absolute means are larger than their algebraic counterparts. Most important, the absolute mean change of the disclosure group is somewhat greater than that of the nondisclosure group, which indicates a smaller change in perceived portfolio riskiness for those corporations affected by the '34 Act. An additional test of this conclusion was made by correlating the $\hat{\beta}_j$ from the pre-*SEC* period with the $\hat{\beta}_j$ from the post-*SEC* period for each group. The correlation coefficient of the pre- and post-*SEC* $\hat{\beta}_j$ (reported in Table 2) is higher for the nondisclosure group, which again indicates a lesser change in the $\hat{\beta}_j$ between periods.

In summary, the tests indicate that the disclosure requirements of the '34 Act had a somewhat lesser effect on the securities of corporations that did not previously disclose sales as compared with those that did. This finding is inconsistent with hypothesis 1) and casts doubt on hypothesis 2).

The stability of the $\hat{\beta}_j$ between periods (or, at the least, a small differential change between the groups) provides support for estimating the $\hat{u}_{jt}$ with the following procedure.[21] Equation (2) was computed for each security that was traded on the *NYSE* for at least five months prior to February 1934 and five months after July 1935, allowing at least ten observations. A total of 487 securities were included under this rule, of which 306 (63 percent) had disclosed their sales and 180 (37 percent) had not prior to the '34 Act. While the

are 1.0115 (.0248) for the disclosure corporations and 1.0006 (.0328) for the nondisclosure companies. The $\hat{\beta}_j$ are lower in both periods for the disclosure group, but insignificantly so.

[20] The standard errors of the means (*SEM*) are relatively small, in part because the sample size (n) is large (SEM = standard derivation/$\sqrt{n-1}$).

[21] The correlation coefficients between the $\hat{\beta}_j$ in the pre- and post-*SEC* periods reported above may not be sufficiently high for some readers to accept this procedure. The alternative procedure would have been to use fewer observations to calculate the statistics, which, I believe, introduces more severe possible biases. In any event, the $\hat{u}_{jt}$ were calculated with $\hat{\beta}_j$'s from the pre-SEC period for the adjustment period and the results were little different from those reported below.

TABLE 3—AVERAGE MONTHLY RESIDUALS IN SUBPERIODS[a]

	Algebraic Means ÷ .001			Absolute Means ÷ .001

7/39 thru 6/41	.077 (.910)	.085 (1.093)	−.008 (1.175)	7.151 (2.961)	6.196 (2.378)	.955 (.743)

[a] Standard deviations shown in parentheses.

number of observations is slightly higher than those used for the $\hat{\beta}_j$ tests, the percentages in the disclosure and nondisclosure groups are almost identical. The $\hat{u}_{jt}$ were computed by running the following "market model" regression for each security

$$r_{jt} = \alpha_j + \beta_j r_{Mt} \tag{5}$$

where t excludes February 1934 through June 1935. The computed $\hat{\alpha}_j$ and $\hat{\beta}_j$ then are used to compute the $\hat{u}_{jt}$ for each month during the "adjustment period," February 1934 through June 1935:

$$\hat{u}_{jt} = \hat{\alpha}_j + \hat{\beta}_j r_{mt} - r_{jt} \tag{5a}$$

where t runs from February 1934 through June 1935. The expected value of the $\hat{u}_{jt}$ is zero in the absence of an unanticipated change in the economic environment, such as the disclosure of previously undisclosed information.

The average (algebraic mean) residuals for each month of the j securities $([\sum_1^n \hat{u}_{jt}]/n$, n = number of securities in each month) were computed for the disclosure and nondisclosure groups. Since several of the hypotheses do not predict a sign of the $\hat{u}_{jt}$, the average absolute residuals for each month $([\sum_1^n |\hat{u}_{jt}|]/n)$ also were computed for each group. Plots of these data were made and summary statistics are given in Table 3 for several subperiods before and after the adjustment period to contrast the behavior of the residuals during that period.

Two basic conclusions can be derived from these data. First, there appears to be somewhat less variance of the residuals of both groups during the months of the adjustment period of February 1934 through June 1935 compared to the following and preceding months. These data indicate that by the time the initial hear-

ings on the Securities Act of 1934 were begun, the impact of the Great Depression on the revaluation of individual shares was largely spent. Second, there is little difference in the behavior of the average residuals of the nondisclosure compared with the disclosure groups. The plots (not presented) show that their residuals behaved almost the same over time, with differences between the two groups being far overshadowed by differences between time periods.

Table 3 is not quite adequate to test the hypothesis that the '34 Act affected each group differently, since the algebraic or absolute mean monthly values and standard deviations over months may not describe the underlying distribution of the individual $\hat{u}_{jt}$. Therefore, Figures 1 and 2 were prepared in which the fractiles (.05 and .95, .10 and .90, .75 and .25, and the median) are plotted for each group over time. If the plot of residuals for one group could have been printed as a transparency and placed over the plot of the other, the reader could see that there is almost no difference in the distribution of residuals between the groups.

The data presented thus far are based on monthly averages of the $\hat{u}_{jt}$. However, it also is necessary to consider the effect of the disclosure statute on individual securities. The possible revaluation of the present value of returns on individual securities need not have taken place entirely in any given month. In addition, it is not clear exactly when corporations made their financial data available as required by the '34 Act. Therefore, the $\hat{u}_{jt}$ were cumulated algebraically for the adjustment period ($\sum_{t=1}^{17} \hat{u}_{jt}$ where t=2/34 through 6/35). As a further check, the $\hat{u}_{jt}$ were cumulated for an additional year ($\sum_{t=1}^{29} \hat{u}_{jt}$ where t=2/34 through 6/36).

Figure 3 presents the data in the form of histograms, in which the distribution of the cumulative residuals for the corporations in the disclosure and nondisclosure group are plotted together. It is clear from these histograms and from the summary statistics (not presented)[22] that there is little difference between the two groups

[22] The algebraic means (and standard deviations) of the cumulative residuals in the February 1934 through June 1935 adjustment period are .0010 (.0307) for the disclosure corporation and .0072 (.0290) for the nondisclosure corporations. In the February 1934 through June 1936 adjustment period, the statistics are −.0004 (.0223) and .0022 (.0206).

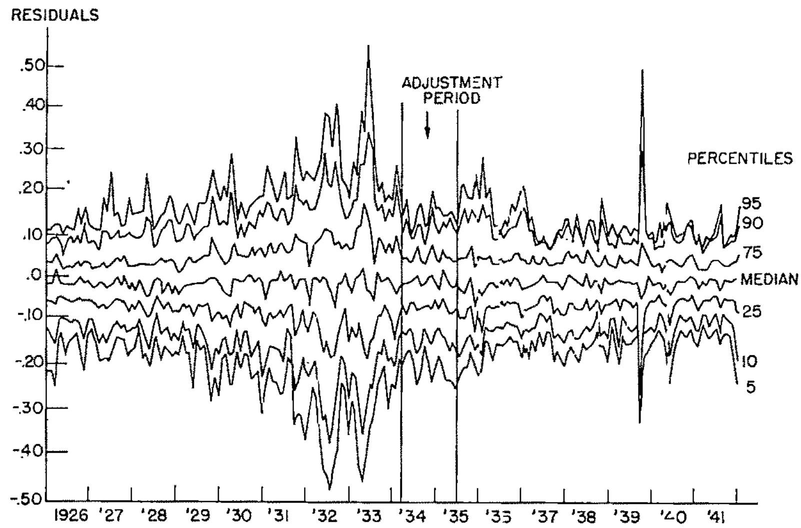

FIGURE 2. DISCLOSURE CORPORATIONS DISTRIBUTION OF RESIDUALS ($\hat{u}_{jt}$)

and that neither group experienced a revaluation of its rates of return that is significantly different from the expected value of zero.

The variance of the residuals of each company, $\sigma^2(\hat{u}_{jt})$ provides an estimate of the volatility of the individual security. A comparison of the mean and distribution of the standard deviations of the residuals of the disclosure and nondisclosure corporations are given in Part A of Table 4. The disclosure corporations show a slightly higher mean standard deviation of residuals in the pre-*SEC* period and, surprisingly, an even greater mean standard deviation in the post-*SEC* period. It is possible, however, that the means of the standard deviations of the $\hat{u}_{jt}$ of each group in the pre- and post-*SEC* periods obscure changes in the variance of individual securities. To test for this possibility, the differences between the standard deviations of the residuals of each company in each period was computed. The mean and distribution of these changes is presented in Part B of Table 4. The mean change is negative for each group, consistent with Part A of the table. Most important, the change in variance of individual stock prices (after accounting for

[a] Shown in percent.

the variance of the stock market as a whole) once the Securities Act of 1934 was effective, is almost the same for those corporations that were and were not affected by the Act.

From these data and the data reported above, I conclude that the '34 Act did not contribute to a reduction in the variance of returns from securities traded on the *NYSE*, as measured by the $\hat{\beta}_j$ (the covariance-variance ratio of security j to the market as a whole) and the standard deviations of the residual returns on securities, $\sigma^2(\hat{u}_{jt})$.[23]

Considering the evidence presented above, I must conclude that the data are consistent only with the hypothesis (5), that the disclosure provisions of the '34 Act were of no apparent value to investors.

VI. Losses by Stockholders

The data used in the tests presented above are of *NYSE* corporations that survived the depression, at least until December 1935 (five months of post-adjustment period data were required for the regressions). A question that should be raised is whether stockholders of corporations that disclosed their sales fared better than those who held stock in nondisclosing corporations. Should this be the case, the findings presented above could be biased because the worst offenders, with respect to disclosure, would have been delisted from the *NYSE*.

To determine whether such was the case, the listing of *NYSE* corporations was traced. The base year chosen was 1929, because this is the last year before the Depression and because I could use a study made by Standard Statistics Company, reported by Lawrence Sloan, pp. 66–74. This study of the income statements of 484 corporations listed on the *NYSE* revealed that 266 (55 percent) reported gross income in 1929 and 218 (45 percent) did not. Table 5 presents the listing history of these securities, showing whether the security was delisted because it went over the counter (*OTC*) or the corporation was merged. Either event is taken to mean a greater than normal loss for stockholders. If this assumption is correct, it is clear that stockholders of corporations that did not disclose gross income in 1929 fared better than those who held stock in the disclosure corporations.

This conclusion is interesting, because it implies that companies that did not disclose their sales were, in fact, better investments than those that did. Such investigations as I could make did not reveal the reasons that some companies disclosed their sales and others did not. A reason consistent with the data would be that those who disclosed had a greater real need

[23] The smaller mean values of the standard deviations of the residuals of securities in both groups in the post-*SEC* compared to the pre-*SEC* period is due primarily to the period of May 1932 through June 1933.

to assure their stockholders of their worth than those who did not.

VII. Investor's Confidence in the Market—Risk and Fairness

A major reason for enactment (and continuance) of the disclosure provisions of the '34 Act was the belief that disclosure was necessary to restore the confidence of investors in the stock market. It is obvious that depressions and the reduction of stock values (either with a "crash" or gradually over a relatively short period) reduce investor confidence and that such events have occurred before and since the passage of the '34 Act and were little affected by it. Therefore, a more meaningful (and charitable) definition of "investor confidence" might be related to the riskiness of returns from securities and to the concept of fairness, that all investors should have equal access to financial information about a company whose shares they own or contemplate buying. Each of these somewhat related concepts is considered in turn.

A reduction of the riskiness of returns, *ceteris paribus*, is considered a benefit because this would reduce the cost of capital to firms and increase investors' confidence in the market. Both assertions are based on the belief that investors are risk averse. (Speculators may prefer risk, but they are

considered by legislators to be a nonpreferred group.) Of course, disclosure, as such, cannot reduce the inherent riskiness of corporations except where disclosure reduces or prevents the risk of fraud. However, disclosure might reduce the risk to the investor of not knowing about significant events (such as a large loss, lawsuit, discovery, etc.) and/or diversifiable risk by reducing the residual variance of security returns (as is discussed above in Section V).

The evidence presented above indicates that disclosure as required by the '34 Act did not reduce fraud, nor did corporations who disclosed their sales fare better in the depression than those who didn't. The data on the variance of the securities of disclosure firms compared to that of nondisclosure firms (Tables 2 and 4), discussed above, indicates that the '34 Act did not have the desired effect on risk (as measured herein). The percentages of large residuals (outlyers) reported in Table 4 also provide evidence on the effectiveness of the '34 Act in reducing the risk of large, presumably unanticipated stock movements. The percentage of outlyers in the pre-*SEC* period was about the same for the disclosure and the nondisclosure firms. However, in the post-*SEC* period, there were relatively fewer mean $\pm 1\sigma$ outlyers for the disclosure group but more mean $\sigma \pm 2$ outlyers for the nondisclosure group.

Some additional evidence on the effect of the '34 Act on the stock market is provided by a study of corporate total capital formation met by stock market issues and publicly sold debt issues compared to private placements in the pre- and post-*SEC* years (through 1954). As I reported in 1969 (see Benston 1969b), the percentage of new issues (net of redemptions) to expenditures on plant and equipment gross and net of price-level adjusted depreciation was the following:[24]

1900–24	30.9 (gross)	58.3 (net)
1919–29	36.8 (gross)	354.3 (net)
1932–38	— (gross)	— (net)
1938–46	6.5 (gross)	51.2 (net)
1946–49	23.1 (gross)	50.2 (net)
1949–54	20.6 (gross)	68.6 (net)

I also found that a ranking of industries by the percentage of private placements to total debt issues was almost exactly the same as a ranking of the extent of bias of the *SEC*'s conservative accounting rules against a fuller reporting of economic events (such as the extent of mining claims, the value of airline routes, etc.). Thus it appears that, contrary to the expectations of its supporters, the '34 Act may have reduced the value of stock markets to corporations and, therefore, to investors.

The concept of fairness is difficult to define operationally. The belief that all investors should have equal access to financial information about a company whose shares they own or contemplate purchasing is perhaps the most important concept, politically, that supports the federal disclosure requirements. While some writers, such as Henry Manne, have argued that investors and the economy are served better when insiders are allowed to profit from information before it is disclosed, legislators argue that all current and potential owners of a corporation have an equal right to information without regard to cost. But since any information must be available to someone before it is known to all, this is a nonoperational concept in its extreme form. And, insofar as the *SEC*'s disclosure requirements require the publication of useless or untimely data (as seems to be the case), the '34 Act has not served its purpose.

Nevertheless, the stock market could be considered "fair" if the prices of securities at any point in time are unbiased estima-

[24] Stock redemptions exceeded new issues in the 1932–1938 period.

tors of their intrinsic values, at least with respect to the financial data which corporations must disclose under the '34 Act. Then whenever an investor decides to buy or sell or hold a security, he can be assured that the market price has discounted completely the financial information. The average investor need not worry about discovering some important financial information about which he is unaware. He will just as often find himself buying or selling a security that is "overvalued" as "undervalued." In this event, the market would be "efficient" in what Fama calls the semi-strong form of the martingale hypothesis.

Fama reviews the theory and evidence on efficient capital markets and concludes that ". . . for the purposes of most investors the efficient markets model seems a good first (and second) approximation to reality. In short, the evidence in support of the efficient markets model is extensive, and (somewhat uniquely in economics) contradictory evidence is sparse" (p. 416). But this evidence is based on data from years after enactment of the '34 Act. The Act may have altered the way in which information gets to the market and the speed with which it is dispersed such that a previously inefficient market became efficient.

The data presented above, that the disclosure required by the '34 Act had no measurable effect on the residual market prices of companies that did and did not disclose their sales, are consistent with the hypothesis that the market was efficient before the legislation was enacted, at least with respect to the financial data.[25] In addition, runs tests on the signs of price changes before 1934 of the securities of the disclosure and nondisclosure corporations revealed that the price changes of both groups confirmed to a random walk.[26] The results of this weaker test of the efficient markets hypothesis is consistent with the belief that the '34 Act did not make the stock market a "fairer game" for investors.

VIII. Summary and Conclusions

The Securities Exchange Act of 1934 is called a "disclosure statute" because its purpose is to force corporations to provide the public with financial data as prescribed by the *SEC*. The Act was passed and extended because of the belief that such disclosure was required to correct the abuses of the pre-Great Depression period, provide information necessary for investors to allocate their resources wisely and efficiently, and make the stock market a "fair game" for the average investor.

A review of the evidence on fraudulently or misleadingly prepared financial statements prior to enactment of the '34 Act revealed very little evidence of abuses in reporting. The assertion by the *SEC* that "pools" and other presumably manipulative devices were made possible by inadequately disclosed financial information is not supported by the data. Proportionately, there was little difference between the reporting practices of corporations whose securities were subject to pools as those who were not.

The value of reported financial data for investors' decisions is based on the as-

[25] These data also are consistent with the hypothesis that published financial data have no information content.

[26] The mean percentage deviations between actual and expected (assuming a random distribution) total runs in the pre-*SEC* and post-*SEC* periods are −1.2 and 4.9 percent for the disclosure corporations and −1.5 and 7.5 percent for the nondisclosure corporations. On a probability basis, the percentage of individual stocks whose runs were significantly different at the 5 percent level from expected are 4.3 and 7.8 for the pre- and post-*SEC* disclosure corporations and 2.3 and 12.2 for the pre- and post-*SEC* nondisclosure corporations. It appears that the security prices of both groups more nearly conformed to a random walk in the pre-*SEC* period than in the post-*SEC* period. Most interesting for present purposes, prices of the securities of corporations that did disclose appear to reflect a less efficient market after the '34 Act became effective than did those of corporations that did not disclose their sales.

sumption that the data the *SEC* requires be made public is useful and timely. The *SEC*'s adherence to historically based, "conservative" accounting procedures reduces the value of the numbers. Nevertheless, the question is an empirical one for which an empirical answer is sought. The extant statistical studies that relate published accounting statement data with stock prices all lead to the conclusion that the data either are not useful or have been fully impounded into stock prices before they are published.[27] Since these studies use relatively simple decision models, evidence on the ability of professional analysts to use financial data for stock choices was reviewed. This evidence supports the conclusion that the accounting statements either are not useful, timely, or both.

However, these findings are based on data from the post-*SEC* period. It may be that the *SEC* has created a climate of confidence in financial data such that the public can accept information as it becomes available during the year. In this event, the annual financial statements, when published, simply confirm that which was previously released, and therefore do not affect stock prices. Investors could believe the information because they know that a reputable government agency, the *SEC*, is concerned about the veracity of financial statements.

The hypothesis was tested by examining statistically the change in riskiness and returns in the stock prices on the *NYSE* before, after, and as a result of the Securities Exchange Act of 1934. Financial statements were available for almost all *NYSE* corporations, but only 62 percent reported their sales or other similarly important information. These corporations are a control sample against which the effects of the '34 Act can be measured. The Sharpe-Markowitz "market model" was used to account for general stock market changes and to provide estimates of the market risk of stocks for each of the samples (disclosure and nondisclosure corporations) in the periods before and after the regulations became effective. Revaluations of securities as a result of the required disclosure of information also were measured with the model. All of the many measurements and analyses show that the '34 Act's financial disclosure requirements had no measurable effect on the securities of the corporation presumedly affected.

The effect of the '34 Act on investors' confidence and on the fairness of the market also was analyzed. Riskiness of securities, as measured by the variance of market prices net of covariance with the market, does not seem to have been reduced by the Act. Nor were the relative percentage of large price movements reduced. Also, the effect of the '34 Act on the capital market may have been perverse, since the percentage of corporate expenditures on plant and equipment financed with new public stock and debt issues was lower in the post- than in the pre-*SEC* decades. With respect to fairness, the evidence that the disclosure requirements did not result in a revaluation of the securities of the affected firms and the conformity of price changes before 1934 to a random walk indicates that the pre-*SEC* stock market was a fair game for investors.

The conclusion of this study, then, must be that the disclosure requirements of the Securities Exchange Act of 1934 had no measurable positive effect on the securities traded on the *NYSE*. There appears to have been little basis for the legislation and no evidence that it was needed or desirable. Certainly there is doubt that more required disclosure is warranted.

[27] An exception may be Beaver's study of preliminary reports.

Optimal Open Market Strategy: The Use of Information Variables

By John H. Kareken, Thomas Muench, and Neil Wallace*

Undeniably, the Federal Open Market Committee (*FOMC*), which decides and executes open market policy for the Federal Reserve System, is much of the time in the dark about what has been going on in the economy. In saying this, we do not mean to be at all derisive. It is simply that the Committee decides policy each day. And yet, most days it does not know the values for the preceding day of all the various economic variables—or, indeed, even the obviously important ones. Thus, only on the first day of the statement week does the Committee know the value of the money stock for the day before. And on how many days of, for example, the calendar quarter does it know, to a reasonable approximation, the value of *GNP* for the day before? Certainly not many.

We can imagine it not mattering in the slightest that the *FOMC* is, as we have said, much of the time in the dark. The consensus judgment of economists is surely, though, that the past influences the present. And information lags being what they are, the presumption must be that most days there are initial conditions which the Committee does not know. So it would seem not entirely idle to investigate how a central bank, or the responsible decision unit thereof, should conduct open market operations if much of the time it is in the dark or, in other words, if most days there are some unknown initial conditions. That is what we have done, although using some simplifying assumptions. In Sections I and II of this paper we present an open market operations strategy for the central bank which much of the time has to contend with unknown initial conditions. Then, in Section III, we compare this strategy with one which we believe is not unlike that of the *FOMC*.

The strategy of Sections I–II is optimal, but so far as we know only on our simplifying assumptions. There are three assumptions which, because they are so unrealistic, we particularly regret having had to make. The first is that the central bank has but one target variable. The second is that the economic structure, although stochastic, is linear. And the third is that the central bank knows with certainty the constants and coefficients of this structure. These assumptions, taken together, imply that the central bank has to optimize only over the current day, not a succession of days extending far (perhaps indefinitely far) into the future.[1] That is why they are so convenient. Still, we should be happier if we had been able to manage with different assumptions—among them, that the central bank is uncertain about the constants and coefficients of the structure constraining it.[2]

What we think of as our information as-

* Staff members of the department of economics, University of Minnesota, and consultants to the Federal Reserve Bank of Minneapolis. All views expressed herein are the sole responsibility of the authors and should not be interpreted as representing those of the Federal Reserve Bank of Minneapolis or the Federal Reserve System.

[1] For us, the "day," an arbitrary but brief stretch of time, is the decision period. There is also the "week," made up of several days, and the "quarter," made up of several weeks.

[2] In the concluding section of the paper, we argue that this is what for realism's sake we should have assumed. It might seem ridiculous to assume that the central bank knows the economic structure which determines, say, calendar-day *GNP*. But if sufficient uncertainty is assumed, this is not so.

sumptions seem to us, however, to be quite realistic. In the economic structure of this paper, which holds over days, there are four variables: a nominal rate of interest; two monetary aggregates, the central bank's portfolio of assets and the stock of deposits; and nominal *GNP*, which we take as the central bank's target variable. And, as we assume, both the interest rate and its asset portfolio are observed by the central bank essentially without lapse of time. At the beginning of each day, it finds out what the values of the interest rate and its asset portfolio were for the day before. (It obviously has to know the value of either the interest rate or its portfolio, since for us it must have used one or the other of these variables as its instrument variable.) But neither the deposit stock nor *GNP* is always observed without lapse of time. The central bank gets observations on the daily deposit stock only at the beginning of each week and observations on daily *GNP* only at the beginning of each quarter. Consequently, only on the first day of the quarter can it determine initial conditions exactly. On all the other days, it cannot. On all the days of the quarter except the first, it must therefore guess initial conditions.

What we show below is that it is optimal for the central bank, in guessing initial conditions for the current day, to use all such observations as have become available since it last decided open market policy. It should always use the most recent observation on the interest rate or its portfolio. And on the first day of the week it should also use the newly received observations on the daily money stock. (Of course, on the first day of the quarter it should use the newly received observations on daily *GNP*.) Precisely how it should use these observations—or how optimal open market policy depends on these observations—is what we explain in some detail in Sections I and II.

We refer to all those variables which the optimizing central bank uses in guessing initial conditions—or, alternatively, in deciding open market policy—as information variables. This is the natural phrase, since observations on these variables constitute information about initial conditions. It would be misleading to refer to any one of them as an intermediate target variable, although this is an oft-heard phrase. For, as we show in Section III, unless the economic structure is very special, the optimizing central bank does not use an intermediate target variable. It does not, that is, start out by calculating a target value or sequence of values for the deposit stock or for any other variable, except of course its true or ultimate target variables (for us, nominal *GNP*), and then strive over several days or weeks for equality between target and actual values. It does, in effect, calculate sequences of values—expected values, however, not target values. Indeed, it does this each day, but only so that subsequently it can compare certain of these values with actual values. This it has to do in deciding open market policy, for comparisons of actual and previously expected values are what determine its guesses about initial conditions. But once having observed discrepancies, it has to calculate new sequences of values—expected values, as we think of them. If there are discrepancies, then initial conditions are not what they were expected to be. Expected values are therefore not what they were expected to be.

Admittedly, there is little point in fussing about descriptive phrases. It is perhaps acceptable to go on using the customary one—intermediate target variable. Those who do should, though, keep in mind that the optimizing central bank likely changes its target value or values each day. It has to make a change, at least on days when it observes discrepancies between actual and previously calculated target (for us, ex-

pected) values. Once discrepancies have been observed, the value of, say, the deposit stock consistent with the desired value of GNP, or any other ultimate target variable, is not what it was. It cannot be, for initial conditions are not as expected.

I. The Optimal Open Market Strategy

In this section, we first set out those simplifying assumptions to which we have referred and then show how, based on these assumptions, the central bank should proceed day by day in the conduct of open market operations. As it turns out, what the central bank should do each day depends on certain expectations. It is in Section II, however, that we provide the formulae for these expectations.

We begin by giving some market equilibrium conditions. The first, for the goods market, is

$$(1) \quad Y_t = \alpha_0 + \alpha_1 R_t + a_t(1), \quad \alpha_1 < 0$$

where Y_t is nominal GNP, R_t is the nominal rate of interest, and $a_t(1)$ is a random disturbance, all for day t. The second equilibrium condition, for the money market, is

$$(2) \quad R_t = \beta_0 + \beta_1 Y_t + \beta_2 P_t + \beta_3 [a_t(2) - a_t(3)]$$

where P_t is the central bank's asset portfolio and $a_t(2)$ and $a_t(3)$ are random disturbances, all for day t.

Underlying the second equilibrium condition are two private-sector structural (demand) equations. One is

$$(3) \quad \begin{aligned} M_t^d &= \alpha_2 + \alpha_3 Y_t + \alpha_4 R_t + a_t(2), \\ &\alpha_3 > 0, \quad \alpha_4 < 0 \end{aligned}$$

where M_t^d is the private sector's desired stock of deposits for day t or, since by assumption there is no coin or currency, its desired stock of money. The other, already having been transformed, is

$$(4) \quad M_t = \alpha_5 + \alpha_6 R_t + \alpha_7 B_t^d + a_t(3), \ \alpha_6, \alpha_7 > 0$$

where M_t is the banking sector's day t stock of deposit liabilities and B_t^d is its desired stock of reserves for day t. The second equilibrium condition follows then from $M_t^d = M_t$ and $P_t = B_t^d$.[3] And, as is easily established,

$$\beta_0 = \frac{\alpha_5 - \alpha_5}{\alpha_6 - \alpha_4}$$

$$\beta_1 = \frac{\alpha_3}{\alpha_6 - \alpha_4} > 0$$

$$\beta_2 = \frac{-\alpha_7}{\alpha_6 - \alpha_4} < 0$$

and

$$\beta_3 = \frac{1}{\alpha_6 - \alpha_4} > 0$$

The central bank is, by assumption, subjectively certain about the α_i. It is not, however, about the $a_t(i)$, which as noted above are random variables. All the central bank knows about the $a_t(i)$ are the stochastic processes which generate them. These are

$$(5) \quad a_t(i) = \rho_i a_{t-1}(i) + u_t(i), \quad |\rho_i| < 1$$

where the $u_t(i)$, random variables, are normally distributed, with

$$E_t u_t(i) = 0$$

and

$$E_t[u_t(i) u_{t+h}(j)] = \begin{cases} V_t u_t(i) = V u(i) & \text{for } i = j \text{ and } h = 0 \\ 0 & \text{otherwise} \end{cases}$$

The symbol $E_t(\cdot)$, which appears very often on the pages following, stands for the expected value of $(\cdot)$ as of the beginning of day t, or for the conditional expectation of $(\cdot)$, which depends on all observations through day t−1.

[3] In equating P_t and B_t^d, we ignore a number of so-called determinants of bank reserves (for example, float).

The past does then influence the present, although in a particularly uncomplicated way. But it is not important that the assumed lag structure is simple. If it were not, there would still be an optimal strategy and its derivation would be essentially the same as that which follows. It is only required that the economic structure be linear.[4]

The central bank's loss function is

$$L = \sum_{1}^{Q} (Y_t - \tilde{Y})^2$$

where Q is the number of days in the quarter and $\tilde{Y}$ is the desired or target value of Y_t.[5] It minimizes expected loss, but subject to equations (1), (2), and (5) and of course the information at hand, which as already explained is most of the time incomplete.

To be more precise, what the central bank minimizes at the beginning of day 1 is E_1L. And since, for $j>0$, $E_{i-j}(\cdot) = E_{t-j}[E_t(\cdot)]$,

$$E_1L = E_1[(Y_1 - \tilde{Y})^2 + E_2[(Y_2 - \tilde{Y})^2 + \dots + E_{Q-1}[(Y_{Q-1} - \tilde{Y})^2 + E_Q(Y_Q - \tilde{Y})^2]]\dots]$$

The central bank minimizes E_1L by first minimizing $E_Q(Y_Q - \tilde{Y})^2$. The minimum of $E_Q(Y_Q - \tilde{Y})^2$, denoted by $\tilde{E}_Q(Y_Q - \tilde{Y})^2$, is in general a function of all initial conditions. Then the central bank minimizes

$$E_{Q-1}[(Y_{Q-1} - \tilde{Y})^2 + \tilde{E}_Q(Y_Q - \tilde{Y})^2]$$

And so it proceeds, until in the end it has minimized

$$E_1[(Y_1 - \tilde{Y})^2 + \tilde{E}_2[(Y_2 - \tilde{Y})^2 + \dots + \tilde{E}_Q[(Y_Q - \tilde{Y})^2]]\dots]$$

That the central bank, proceeding in the way described, does indeed minimize E_1L is established by induction.[6] Whatever the outcomes for days 1, 2, . . . , Q−1 or the observations at hand at the beginning of day Q,

$$\tilde{E}_Q(Y_Q - \tilde{Y})^2 \leq \overline{E}_Q(Y_Q - \tilde{Y})^2$$

where $\overline{E}_Q$ is the expected loss associated with any policy whatever for day Q.

We must now establish that

if (a) $\tilde{E}_{t+1}(\sim) \leq \overline{E}_{t+1}(-)$

where

$$\tilde{E}_{t+1}(\sim) = \tilde{E}_{t+1}[(Y_{t+1} - \tilde{Y})^2 + \tilde{E}_{t+2}[(Y_{t+2} - \tilde{Y})^2 + \dots + \dots \tilde{E}_Q(Y_Q - \tilde{Y})^2]]\dots]$$

and

$$\overline{E}_{t+1}(-) = \overline{E}_{t+1}[(Y_{t+1} - \tilde{Y})^2 + \overline{E}_{t+2}[(Y_{t+2} - \tilde{Y})^2 + \dots + \overline{E}_Q(Y_Q - \tilde{Y})^2]]\dots],$$

then (b) $\tilde{E}_t(\sim) \leq \overline{E}_t(-)$

By hypothesis (inequality (a)) and the nature of the expectations operator,

$$\overline{E}_t[\tilde{E}_{t+1}(\sim)] \leq \overline{E}_t[\overline{E}_{t+1}(-)]$$

Adding $\overline{E}_t(Y_t - \tilde{Y})^2$ to both sides,

$$\overline{E}_t[(Y_t - \tilde{Y})^2 + \tilde{E}_{t+1}(\sim)] \leq \overline{E}_t(-)$$

The desired conclusion (inequality (b)) follows, since by definition $\tilde{E}_t(\sim)$ is less

[4] Nor do the stochastic processes have to be first-order Markovian. Incidentally, it is easy enough to do away with the influence of the past. One has only to assume, for all i, that $\rho_i = 0$.

[5] We might have assumed the central bank's loss function to be

$$L = \left(\sum_{1}^{Q} Y_t - \sum_{1}^{Q} \tilde{Y}\right)^2$$

where $\Sigma_1^Q Y_t$ is the familiar quarterly *GNP*. It seemed unreasonable, though, to force the central bank only to "average" the Y_t or, in effect, to make it not care about within-quarter fluctuations of Y_t. The assumption of a constant target value, $\tilde{Y}$, is of no consequence. We could easily have managed with an arbitrary path of target values, $\tilde{Y}_t$.

[6] Those familiar with dynamic programming will recognize the following proof.

than or equal to the left-hand side of this inequality.

The central bank has two possible instrument variables, however, P, its asset portfolio and R, the nominal interest rate. It therefore does not simply minimize expected loss by choice of a value for a given instrument variable. Rather, it minimizes by choice of a value for R and a value for P and then by comparing its two minimum expected losses.

With R as the instrument variable, the reduced-form equation for Y_t is equation (1) or, by equations (5),

$$Y_t = \alpha_0 + \alpha_1 R_t + \rho_1 a_{t-1}(1) + u_t(1) \tag{6}$$

By definition, though, $a_{t-1}(i)$ is the sum of $E_t a_{t-1}(i)$, the expectation of $a_{t-1}(i)$ as of the beginning of day t, and a forecast error $e_t(i)$, the deviation of $a_{t-1}(i)$ from that expectation; that is

$$a_{t-1}(i) = E_t a_{t-1}(i) + e_t(i) \tag{7}$$

Therefore,

$$\begin{aligned} Y_t = \alpha_0 + \alpha_1 R_t + \rho_1 E_t a_{t-1}(1) \\ + \rho_1 e_t(1) + u_t(1) \end{aligned} \tag{8}$$

And so

$$\begin{aligned} &E_Q(Y_Q - \bar{Y})^2 \\ &= [\bar{Y} - \alpha_0 - \alpha_1 R_Q - \rho_1 E_Q a_{Q-1}(1)]^2 \\ &\quad + E_Q[\rho_1 e_Q(1)^2 + u_Q(1)^2] \end{aligned}$$

Since the second of the terms on the right-hand side of the equation does not depend on R_Q, the optimal or minimizing value of R_Q satisfies the equation

$$\bar{Y} = \alpha_0 + \alpha_1 R_Q + \rho_1 E_Q a_{Q-1}(1) \tag{9}$$

Also,

$$\begin{aligned} \tilde{E}_Q(Y_Q - \bar{Y})^2 &= \rho_1^2 E_Q e_Q(1)^2 + E_Q u_Q(1)^2 \\ &= \rho_1^2 \Pi_Q(1, 1) + \Phi(1, 1) \end{aligned}$$

where Φ is the variance-covariance matrix of the $u_t(i)$ and Π_t is the variance-covariance matrix of the $e_t(i)$.[7]

[7] That is, $\Pi_t = E_t(e_t e_t')$ where $e_t' = [e_t(1), e_t(2), e_t(3)]$.

With P as the instrument variable, the reduced-form equation for Y_t is

$$\begin{aligned} Y_t = \delta_0 + \delta_1 P_t + \delta_2 a_t(1) \\ + \delta_3[a_t(2) - a_t(3)] \end{aligned} \tag{10}$$

or, by equations (5),

$$Y_t = \delta_0 + \delta_1 P_t + \Delta_\rho' a_{t-1} + \Delta' u_t \tag{11}$$

where

$$\begin{aligned} \Delta' &= (\delta_2, \delta_3, -\delta_3) \\ \Delta_\rho' &= (\rho_1\delta_2, \rho_2\delta_3, -\rho_3\delta_3) \\ a_t' &= [a_t(1), a_t(2), a_t(3)] \\ u_t' &= [u_t(1), u_t(2), u_t(3)] \\ \delta_0 &= \frac{\alpha_0 + \alpha_1\beta_0}{1 - \alpha_1\beta_1} \\ \delta_1 &= \frac{\alpha_1\beta_2}{1 - \alpha_1\beta_1} > 0 \\ \delta_2 &= \frac{1}{1 - \alpha_1\beta_1} > 0 \end{aligned}$$

and

$$\delta_3 = \frac{\alpha_1\beta_3}{1 - \alpha_1\beta_1} < 0$$

Then, by equations (7),

$$\begin{aligned} E_Q(Y_Q - \bar{Y})^2 &= (\bar{Y} - \delta_0 - \delta_1 P_Q - \Delta_\rho' E_Q a_{Q-1})^2 \\ &\quad + E_Q(\Delta' u_Q u_Q' \Delta + \Delta_\rho' e_Q e_Q' \Delta_\rho) \end{aligned}$$

It follows that the optimal value of P_Q satisfies the equation

$$\bar{Y} = \delta_0 + \delta_1 P_Q + \Delta_\rho' E_Q a_{Q-1} \tag{12}$$

and

$$\tilde{E}_Q(Y_Q - \bar{Y})^2 = \Delta'\Phi\Delta + \Delta_\rho'\Pi_Q\Delta_\rho$$

The central bank therefore uses R or P as its instrument variable for day Q, depending on whether

$$\begin{aligned} &\Phi(1, 1) + \rho_1^2 \Pi_Q(1, 1) \\ &\qquad \lesseqgtr \Delta'\Phi\Delta + \Delta_\rho'\Pi_Q\Delta_\rho \end{aligned} \tag{13}$$

If it uses R, then open market policy is

determined by equation (9). And if it uses P, then open market policy is determined by equation (12). It follows that $E_{Q-1}[(Y_{Q-1}-\bar{Y})^2+\tilde{E}_Q(Y_Q-\bar{Y})^2]$ is either

$$E_{Q-1}[(Y_{Q-1} - \bar{Y})^2 + \Phi(1, 1) + \rho_1^2\Pi_Q(1, 1)]$$

or

$$E_{Q-1}[(Y_{Q-1} - \bar{Y})^2 + \Delta'\Phi\Delta + \Delta_\rho'\Pi_Q\Delta_\rho]$$

But Φ is a constant. And as we show below (Section II), so is Π_t; that is to say, for all t, it is independent of the sequence of instrument variable choices and values up through day t−1. Consequently, the day Q−1 choices of instrument variable and value can affect only $E_{Q-1}(Y_{Q-1}-\bar{Y})^2$ and thus should be made so as to minimize this term. The minimization problem of day Q−1 is therefore exactly the same as that of day Q. The day Q−1 analogue of equation (9) therefore determines the optimal value of R_{Q-1}. The day Q−1 analogue of equation (12) determines the optimal value of P_{Q-1}. And the analogue of inequalities (13) determines whether R or P is the instrument variable for day Q−1.

We might continue through the minimization process, but likely it has already become apparent that, with Π_t independent of past instrument variable choices and values, there is only one term of

$$E_t[(Y_t - \bar{Y})^2 + \tilde{E}_{t+1}[(Y_{t+1} - \bar{Y})^2 + \dots + \tilde{E}_Q(Y_Q - \bar{Y})^2]] \dots],$$

namely $E_t(Y_t-\bar{Y})^2$, that depends on policy for day t. The optimal value of R_t, denoted by $\tilde{R}_t$, is therefore the solution of the day t analogue of equation (9). That is

$$\text{(14)} \quad \tilde{R}_t = [\bar{Y} - \alpha_0 - \rho_1 E_t a_{t-1}(1)]/\alpha_1$$

And the optimal value of P_t, denoted by $\tilde{P}_t$, is the solution of the day t analogue of equation (12),

$$\text{(15)} \quad \tilde{P}_t = (\bar{Y} - \delta_0 - \Delta_\rho' E_t a_{t-1})/\delta_1$$

Finally, the central bank uses R or P as its instrument variable, depending on whether

$$\text{(16)} \quad \Phi(1, 1)+\rho_1^2\Pi_t(1, 1) \lesseqgtr \Delta'\Phi\Delta+\Delta_\rho'\Pi_t\Delta_\rho$$

If the central bank always had complete information, then $\Pi_t=0$ would hold for all t. And it would use R or P as its instrument variable, depending on whether[8]

$$\Phi(1, 1) \lesseqgtr \Delta'\Phi\Delta$$

There is therefore an easy interpretation of the second terms on both the left- and right-hand sides of inequality (16). With R as the instrument variable, there is some additional expected loss, $\rho^2\Pi_t(1, 1)$, attributable to the central bank not having complete information or to the existence of our assumed information lags. And with P as the instrument variable, there is also some additional expected loss, $\Delta_\rho'\Pi_t\Delta_\rho$, attributable to the central bank not having complete information.

II. The Central Bank's Expectations and a Proof of Independence

To decide open market policy for day t, the central bank has to know $E_t a_{t-1}$ and Π_t. In this section, we therefore derive formulae for these expectations and then, making use of the formula for Π_t, give an inductive proof that Π_t is independent of past policy decisions.

As is well known, if Y_{t-1} and $X_{t-1}(1)$, $X_{t-1}(2), \dots, X_{t-1}(N)$ are normal random variables and the $X_{t-1}(i)$ the only variables observed at the beginning of day t are uncorrelated with each other, then the expectation of Y_{t-1} with the $X_{t-1}(i)$ known, or as of the beginning of day t, is

$$\text{(17)} \quad E_t Y_{t-1} = E_{t-1} Y_{t-1} + \sum_i \eta_t(i)[X_{t-1}(i) - E_{t-1}X_{t-1}(i)]$$

[8] If $\rho_i=0$ for all i, then the central bank would effectively always have complete information, even with information lags, and it would use this inequality in making its instrument variable choice. This inequality is essentially like those given by William Poole, p. 206, and Kareken, p. 389.

$E_{t-1}Y_{t-1}$ is the expectation of Y_{t-1} with the $X_{t-1}(i)$ unknown, or as of the beginning of day t−1; $E_{t-1}X_{t-1}(i)$ is the expectation of $X_{t-1}(i)$ with Y_{t-1} unknown, or as of the beginning of day t−1; and

$$\eta_t(i) = C_{t-1}[Y_{t-1}, X_{t-1}(i)]/V_{t-1}X_{t-1}(i) \equiv E_{t-1}[y_{t-1}x_{t-1}(i)]/E_{t-1}x_{t-1}(i)^2$$

where

$$y_{t-1} = Y_{t-1} - E_{t-1}Y_{t-1}$$

and

$$x_{t-1}(i) = X_{t-1}(i) - E_{t-1}X_{t-1}(i)$$

As is also well known, the residual from the expectation given by equation (17), that is, $Y_{t-1}-E_tY_{t-1}$, is independent of the $X_{t-1}(i)$. We use this result below in deriving the formulae for Π_t.

At the beginning of day t, then, the central bank uses equations like equation (17) to determine the $E_ta_{t-1}(i)$. Its information variables, the counterparts of the $X_{t-1}(i)$, are not the same, however, for all t. For one thing, it does not necessarily use the same variable as its instrument variable on days t and t+1. And an instrument variable cannot be an information variable, for by definition its expected value as of the beginning of day t and its actual value for day t are the same.[9] Also, recall our information assumptions. At the beginning of day t, where t=1, 2, . . . , Q, P_{t-1} and R_{t-1} are known. But M_{t-1} is known only for t=1, ω+1, 2ω+1, . . . , (s−1)ω+1, there being ω days in a week and s weeks in the quarter. And Y_{t-1} is known only for t=1. It is not therefore simply a matter of deriving one set of formulae, the counterparts of equation (17), which hold for all t. There are several sets of formulae and to derive them we have to consider the central bank's situation at the beginning of the first day of the quarter, the second or any subsequent day of the first week and the first day of the second or any other week of the quarter.

A. *Days of the First Week*

The first day of the quarter (t=1) is decidedly special. At its beginning, the central bank—knowing P_0, R_0, M_0, and Y_0—is able actually to calculate a_0. In a manner of speaking, therefore, it uses equations (1), (3), and (4) to determine $E_1a_0=a_0$. And, of course, $\Pi_1=0$.

We now show how the central bank obtains E_ta_{t-1} and Π_t, given that it has $E_{t-1}a_{t-2}$ and Π_{t-1}. At the beginning of day t, where $2\leqq t\leqq\omega$, the central bank gets observations on P_{t-1} and R_{t-1}. One of these observations provides no information about a_{t-1}, though, since the central bank must have used either P or R as its instrument variable for day t−1. If it used P, then by equation (17)

$$(18)\quad E_ta_{t-1}(i) = E_{t-1}a_{t-1}(i) + \phi_t(i)r_{t-1}$$

where

$$r_{t-1} = R_{t-1} - E_{t-1}R_{t-1}$$
$$\phi_t(i) = C_{t-1}[a_{t-1}(i), R_{t-1}]/V_{t-1}R_{t-1}$$

and, by equations (5),

$$(19)\qquad E_{t-1}a_{t-1}(i) = \rho_iE_{t-1}a_{t-2}(i)$$

Now, the reduced-form equation for R_{t-1}, derived from equations (1) and (2), is

$$(20)\quad R_{t-1} = \gamma_0 + (\delta_1/\alpha_1)P_{t-1} + \Gamma'a_{t-1}$$

where

$$\Gamma' = (\beta_1\delta_2, \delta_3/\alpha_1, -\delta_3/\alpha_1)$$

and

$$\gamma_0 = \frac{\beta_0+\alpha_0\beta_1}{1-\alpha_1\beta_1}$$

Therefore, by equation (19),

$$(21)\qquad E_{t-1}R_{t-1} = \gamma_0 + (\delta_1/\alpha_1)P_{t-1} - \Gamma_\rho' E_{t-1}a_{t-2}$$

[9] We show below, however, that E_ta_{t-1} and Π_t are the same, whether P was used as the instrument variable for day t−1 or R was.

where

$$\Gamma_\rho' = (\rho_1\beta_1\delta_2,\ \rho_2\delta_3/\alpha_1,\ -\rho_3\delta_3/\alpha_1)$$

Since r_{t-1} is the difference between R_{t-1} and $E_{t-1}R_{t-1}$, it follows from equations (5) and (7) and (20), and (21) that

$$(22) \qquad r_{t-1} = \Gamma_\rho' e_{t-1} + \Gamma' u_{t-1}$$

Also, by equations (5), (7), and (19),

$$(23) \quad a_{t-1}(i) - E_{t-1}a_{t-1}(i) = \rho_i e_{t-1}(i) + u_{t-1}(i),$$

so

$$(24) \quad C_{t-1}[a_{t-1}(i), R_{t-1}] = \Gamma_i Vu(i) + \rho_i \Gamma_\rho' \Pi_{t-1}(i)$$

where Γ_i is the ith element of Γ and $\Pi_{t-1}(i)$ is the ith column of Π_{t-1},

$$(25) \quad V_{t-1}R_{t-1} = \Gamma'\Phi\Gamma + \Gamma_\rho'\Pi_{t-1}\Gamma_\rho$$

and

$$(26) \quad \phi_t(i) = \frac{\Gamma_i Vu(i) + \rho_i \Gamma_\rho' \Pi_{t-1}(i)}{\Gamma'\Phi\Gamma + \Gamma_\rho'\Pi_{t-1}\Gamma_\rho}$$

Finally, by equations (5), (18), and (23),

$$(27) \quad e_t(i) = \rho_i e_{t-1}(i) - \phi_t(i) r_{t-1} + u_{t-1}(i)$$

And since the $e_t(i)$ are independent of r_{t-1},

$$E_t(e_t e_t') = E_{t-1}(e_t e_t')$$

In consequence,

$$(28) \quad \Pi_t(i,j) = \rho_i\rho_j \Pi_{t-1}(i,j) + E[u(i)u(j)] - \phi_t(i)\phi_t(j) V_{t-1}R_{t-1}$$

or, by equations (25) and (26), we may derive equation (29) shown below.

If P was the instrument variable for day t−1, then the appropriate expectations for deciding open market policy at the beginning of day t are those of equations (18) and (29). These, however, are also the appropriate expectations if R was the instrument variable for day t−1. If it was, then by equation (17)

$$(30) \quad E_t a_{t-1}(i) = E_{t-1}a_{t-1}(i) + \theta_t(i) p_{t-1}$$

But there is a reduced-form equation for P_{t-1}, obtainable from equation (20),

$$(31) \quad P_{t-1} = -(\alpha_1/\delta_1)(\gamma_0 - R_{t-1} + \Gamma' a_{t-1})$$

so

$$(32) \quad p_{t-1} = -(\alpha_1/\delta_1)(\Gamma_\rho' e_{t-1} + \Gamma' u_{t-1})$$

In words, p_{t-1} is simply a multiple of the discrepancy, r_{t-1}, which would have been observed had P been used as the instrument variable (see equation (22)). And since $a_{t-1} - E_{t-1}a_{t-1}$ is independent of the instrument variable choice and value of day t−1 (see equation (23)), it follows that $\theta(i) = -(\delta_1/\alpha_1)\phi(i)$ and, from this equality, that $E_t a_{t-1}$ and Π_t are the same whether P or R was used as the instrument variable for day t−1.[10]

Thus, assuming known unique values of $E_{t-1}a_{t-2}$ and of Π_{t-1}, values assumed to be independent of policy decisions up through day t−2, we have now found unique values of $E_t a_{t-1}$ and of Π_t. These depend on those prior expectations, on certain functions of day t−1 outcomes, and on the parameters of the structure (including the $Vu(i)$), but not on the day t−1 policy decision. For Π_t, this is clear from inspection of equations (29); for $E_t a_{t-1}$, one must inspect equations (18), (19), (22), and (26). Since we showed at the outset of this section that the $E_1 a_0$ and Π_1 are independent of policy

[10] This result is easily checked. One has only to redo our derivations, starting, however, with equations (30) and (31). It is perhaps not surprising that $E_t a_{t-1}$ and Π_t are the same, no matter which variable, P or R, was chosen as instrument variable at the beginning of day t−1. These variables are linearly related (equation (20)), and the disturbance in the relationship is independent of which variable was chosen as the instrument variable.

$$(29) \quad \Pi_t(i,j) = \rho_i\rho_j\Pi_{t-1}(i,j) + E[u(i)u(j)] - \frac{[\Gamma_i Vu(i) + \rho_i\Gamma_\rho'\Pi_{t-1}(i)][\Gamma_i Vu(j) + \rho_j\Gamma_\rho'\Pi_{t-1}(j)]}{\Gamma'\Phi\Gamma + \Gamma_\rho'\Pi_{t-1}\Gamma_\rho}$$

up through day 0, it follows that $E_t a_{t-1}$ and Π_t are independent of the entire sequence of policy decisions up through day $t-1$. That this is true for Π_t can be seen in a slightly different and perhaps more revealing way. Because all of the parameters of the economic structure, including the $Vu(i)$ are known at the beginning of day 1, the central bank, using equations (29), is at that time able to calculate all Π_t.[11]

Strictly speaking, the proof and the formulae we have provided are only for $1 \leqq t \leqq \omega$. It is easy enough, however, to extend the proof for $t > \omega$. Moreover, as will be apparent, the formulae found here apply for second and subsequent days of all the remaining weeks. Only the formulae for the first day of the second and following weeks are missing.

B. *The First Day of the Second Week*

At the beginning of the first day of the second week, day $\omega+1$, the central bank gets observations on the daily deposit stock for the first week. And knowing $M_1, M_2, \ldots, M_\omega$, it revises its expectations of a_{t-1} for $2 \leqq t \leqq \omega$. It puts itself back at the beginning of day 2 and, using observations on M_1 and P_1 or R_1, calculates revised expectations of a_1, denoted by $E_2^* a_1$. Then it puts itself at the beginning of day 3 and, using observations of M_2 and P_2 or R_2, calculates the revised expectation $E_3^* a_2$. And in the end, having calculated $E_t^* a_{t-1}$ for $2 \leqq t \leqq \omega$, it comes to expectations of a_ω, which is in part what it needs to determine open market policy for day $\omega+1$.

If P was the instrument variable for day $t-1$, then for day t the central bank's information variables are R and M. To use equations similar to equation (17) to determine $E_t^* a_{t-1}$, it has to have information variables which are uncorrelated. Obviously, R_{t-1} and M_{t-1} are correlated. But there are transforms,

$$Z_{t-1}(1) = \overset{*}{m}_{t-1} - \alpha_6 \overset{*}{r}_{t-1} \tag{33}$$

and

$$Z_{t-1}(2) = (\delta_3/\alpha_1) Z_{t-1}(1) + \overset{*}{r}_{t-1} \tag{34}$$

which are uncorrelated.

By equations (4) and (20), the reduced-form equation for M_{t-1} is

$$\begin{aligned} M_{t-1} = \alpha_5 + (\alpha_7 + \alpha_6\delta_1/\alpha_1)P_{t-1} \\ + \alpha_6 \Gamma' a_{t-1} + a_{t-1}(3); \end{aligned} \tag{35}$$

therefore,

$$\begin{aligned} \overset{*}{m}_{t-1} &\equiv M_{t-1} - \overset{*}{E}_{t-1} M_{t-1} \\ &= \alpha_6 \Gamma'(a_{t-1} - \overset{*}{E}_{t-1} a_{t-1}) \\ &\quad + a_{t-1}(3) - \overset{*}{E}_{t-1} a_{t-1}(3) \end{aligned} \tag{36}$$

But since

$$\begin{aligned} a_{t-1}(i) - \overset{*}{E}_{t-1} a_{t-1}(i) \\ = \rho_i \overset{*}{e}_{t-1}(i) + u_{t-1}(i) \end{aligned} \tag{37}$$

it follows that

$$\begin{aligned} \overset{*}{m}_{t-1} = \alpha_6(\Gamma_\rho' \overset{*}{e}_{t-1} + \Gamma' u_{t-1}) \\ + \rho_3 \overset{*}{e}_{t-1}(3) + u_{t-1}(3) \end{aligned} \tag{38}$$

And by the analogue of a previous argument (see the derivation of equation (22)),

$$\overset{*}{r}_{t-1} = \Gamma_\rho' \overset{*}{e}_{t-1} + \Gamma' u_{t-1}, \tag{39}$$

so

$$Z_{t-1}(1) = \rho_3 \overset{*}{e}_{t-1}(3) + u_{t-1}(3) \tag{40}$$

and

$$Z_{t-1}(2) = \Gamma_\rho^{*\prime} \overset{*}{e}_{t-1} + \Gamma^{*\prime} u_{t-1} \tag{41}$$

where

$$\Gamma^{*\prime} = (\beta_1\delta_2, \delta_3/\alpha_1, 0)$$

and[12]

$$\Gamma_\rho^{*\prime} = (\rho_1\beta_1\delta_2, \rho_2\delta_3/\alpha_1, 0)$$

[11] Note that there is no circularity of reasoning, since in this section we have not assumed optimality of policy, nor, in fact, anything about policy, except that each day either P or R is used as the instrument variable.

[12] That $Z_{t-1}(1)$ and $Z_{t-1}(2)$ are uncorrelated is estab-

Now, since $Z_{t-1}(1)$ and $Z_{t-1}(2)$ are uncorrelated,

$$E_t^* a_{t-1}(i) = E_{t-1}^* a_{t-1}(i) + \sum_{k=1}^{2} \phi_t^*(i, k) Z_{t-1}(k) \tag{42}$$

where

$$\phi_t^*(i, k) = \frac{C_{t-1}^*[a_{t-1}(i), Z_{t-1}(k)]}{V_{t-1}Z_{t-1}(k)}$$

As is readily verified,

$$\phi_t^*(i, 1) = \begin{cases} 0 & \text{for } i = 1, 2 \\ 1 & \text{for } i = 3 \end{cases}$$

and

$$\phi_t^*(i, 2) = \begin{cases} \dfrac{\rho_i \Gamma_p^{*\prime} \Pi_{t-1}^*(i) + \Gamma_i^{*\prime} V u(i)}{\Gamma_p^{*\prime} \Pi_{t-1}^* \Gamma_p^* + \Gamma^{*\prime} \Phi \Gamma^*} & \text{for } i = 1, 2 \\ 0 \quad \text{for } i = 3 \end{cases}$$

where $\Pi_{t-1}^*(i)$ is the ith column of Π_{t-1}^*, the variance-covariance matrix of e_{t-1}^* and Γ_i^* is the ith element of Γ^*.

And by equations (37) and (42),

$$e_t^*(i) = \rho_i e_{t-1}^*(i) - \sum_{k=1}^{2} \phi_t^*(i, k) Z_{t-1}(k) + u_{t-1}(i), \tag{43}$$

so

$$\Pi_t^*(i, j) = \begin{cases} \rho_i \rho_j \Pi_{t-1}^*(i, j) + E[u(i)u(j)] \\ \quad - \phi_t^*(i, 2)\phi_t^*(j, 2) V_{t-1}^* Z_{t-1}(2) & \text{for } i, j \neq 3 \\ 0 \quad \text{for } i = 3 \text{ or } j = 3 \end{cases} \tag{44}$$

There is the possibility, however, of the central bank having used R as its instrument variable for day t−1. If it did, then P and M are its information variables. The uncorrelated transforms are

$$Z_{t-1}(3) = m_{t-1}^* + (\alpha_6 \delta_1/\alpha_1) p_{t-1}^* \tag{45}$$

and

$$Z_{t-1}(4) = (\delta_3/\delta_1) Z_{t-1}(3) - p_{t-1}^* \tag{46}$$

where p_{t-1}^* is the analogue of p_{t-1}. But $Z_{t-1}(3) = Z_{t-1}(1)$ and $Z_{t-1}(4) = (\alpha_1/\delta_1) Z_{t-1}(2)$, so $E_t^* a_{t-1}$ is the same, whether P was chosen as the instrument variable at the beginning of day t−1 or R was.

The central bank, at the beginning of day $\omega+1$, uses equations (42) and (44)—but, as already indicated, repeatedly—to get the necessary expectations. Its situation at the beginning of day $2\omega+1$, or any other first day of the week, is exactly the same, however, as its situation at the beginning of day $\omega+1$, so we have now completed our task of providing all the required expectations formulae.

C. *A Generalization*

In this subsection, we provide the expectations formulae for the central bank which is constrained by an economic structure which, although also linear, is more complicated than that of Section I. These formulae are easy generalizations of those derived above. Setting them out, we nevertheless make an important point: that in deciding open market policy, the optimizing central bank "looks at everything." This point has been made by others, but perhaps not fully justified.

We assume here that there are K inter-

---

lished by the following argument. Because a_0 is known, $e_1^*(3) = 0$. Therefore, by equation (40), $Z_1(1) = u_1(3)$. And since $Z_1(1)$ is known at the beginning of day 2, $u_1(3)$ is too. Consequently,

$$E_2^* a_1(3) = E_2^*[\rho_3 a_0(3) + u_1(3)] = a_1(3)$$

and $e_2^*(3) = 0$, so $u_2(3)$ is known as of the beginning of day 3. More generally, $Z_t(1) = u_t(3)$ and $e_t^*(3) = 0$ for $t \leq \omega$, so as alleged, $Z_{t-1}(1)$ and $Z_{t-1}(2)$ are uncorrelated. It is a consequence of the particular economic structure of Section I, however, that $e_t^*(3) = 0$ and that $u_t(3)$ is known as of the beginning of day t+1. In general, it is not possible to identify any of the day t disturbances at the beginning of day t+1. But this does not matter, since for any linear economic structure there exist uncorrelated transforms of all the natural information variables that contain all the information.

est rates, the kth of which is $R_t(k)$, and N monetary aggregates, the nth of which is $M_t(n)$. At the beginning of day t where $t=1, 2, \ldots, Q$ the central bank observes P_{t-1} and $R_{t-1}(k)$, $k=1, 2, \ldots, K$. And at the beginning of day t where $t=1, \omega+1, \ldots, (s-1)\omega+1$ it observes $M_{t-1}(n)$, $M_{t-2}(n), \ldots, M_{t-\omega}(n)$, $n=1, 2, \ldots, N$.

It is enough to give the formulae which apply if P was the instrument variable for day $t-1$. Thus,

$$E_t a_{t-1}(i) = E_{t-1}a_{t-1}(i) + \sum_{k=1}^{K} \psi_t(i, k) Z_{t-1}(k) \tag{47}$$

for $i=1, 2, \ldots, I \geq K+N+1$ and $t=2, 3, \ldots, \omega, \omega+2, \ldots, Q$ where $Z_{t-1}(k)$, $k=1, 2, \ldots, K$ are independent linear transforms of the $r_{t-1}(k)$ and

$$\psi_t(i, k) = \frac{C_{t-1}[a_{t-1}(i), Z_{t-1}(k)]}{V_{t-1}Z_{t-1}(k)}$$

Also,

$$\Pi_t(i, j) = \rho_i\rho_j\Pi_{t-1}(i, j) + E[u(i)u(j)] - \sum_{k=1}^{K} \psi_t(i, k)\psi_t(j, k) V_{t-1}Z_{t-1}(k) \tag{48}$$

And, finally, for $t=\omega+1, 2\omega+1, \ldots, (s-1)\omega+1$,

$$E_t a_{t-1}(i) = \overset{*}{E}_{t-1}a_{t-1}(i) + \sum_{k=1}^{K+N} \overset{*}{\psi}_t(i, k) \overset{*}{Z}_{t-1}(k) \tag{49}$$

where the $Z^*_{t-1}(k)$ are independent linear transforms of the $r^*_{t-1}(k)$ and the $m^*_{t-1}(k)$ and

$$\overset{*}{\psi}_t(i, k) = \frac{\overset{*}{C}_{t-1}[a_{t-1}(i), \overset{*}{Z}_{t-1}(k)]}{V^*_{t-1}Z^*_{t-1}(k)}$$

and

$$\overset{*}{\Pi}_t(i, j) = \rho_i\rho_j\overset{*}{\Pi}_{t-1}(i, j) + E[u(i)u(j)] - \sum_{k=1}^{K+N} \overset{*}{\psi}_t(i, k)\overset{*}{\psi}_t(j, k) \overset{*}{V}_{t-1}\overset{*}{Z}_{t-1}(k) \tag{50}$$

In deciding open market policy at the beginning of day t, the optimizing central bank does then use all of its most recent observations, those on interest rates and, if there are any, those on monetary aggregates. So much is clear from equations (47) and (49). Nor does it respond to or "weight" its most recent observations in an arbitrary way. The weights are determined by the economic structure.

III. An Alternative Strategy

We have but one remaining task: to evaluate an alternative strategy for open market operations. This strategy, which we think of as the intermediate target variable strategy, is in our judgment the strategy the *FOMC* would be using if it were not at all concerned about day-to-day and week-to-week changes in interest rates and if the simplifying assumptions of Section I were satisfied. It is, we believe, essentially like the *FOMC*'s actual strategy.[13] That of course is why we bother to evaluate it and why in this section we portray the *FOMC* as using it.

The *FOMC* has a target path for Y—a sequence of target values, that is, one for each day of the quarter—which is determined at the very beginning of the quarter. As above, we take this target path to be $Y(t)=\bar{Y}$, for all t. The question is how the *FOMC* goes about trying to realize its objective, which is equality between actual Y and $\bar{Y}$ for every day t of the quarter. To facilitate understanding, we first provide a

[13] In formulating our alternative or intermediate target variable strategy, we tried to approximate the *FOMC* strategy of 1970–71, which has been described by, among others, Stephen Axilrod, Alan Holmes, and Paul Meek and Rudolf Thumberg. There have been indications that early in 1972 the *FOMC* changed its strategy, but not so far as we are concerned in an essential way. What the *FOMC* evidently did in January–February 1972 was switch from using the federal funds rate as its operating variable to using a reserves aggregate. To all appearances, however, it did not give up the use of certain variables (for example, the narrowly defined stock of money) as intermediate target variables. And here that is what is important.

rather loose description of how the *FOMC* proceeds. Thereafter, though, we provide a precise description. We do this by actually deriving the sequence of desired or target values for the *FOMC*'s instrument variable, denoted by $\bar{P}(t)$, which is implied by $\bar{Y}$. Then we compare $\bar{P}(t)$ and $\tilde{P}(t)$, the latter being our optimal value of P for day t, and in so doing evaluate the *FOMC* strategy.

The *FOMC* first decides on a target value for Y. Then, using this value, it goes on and determines a target path or sequence of target values for M, its intermediate target variable. And, what is most important, it does this at the very beginning of the quarter. Nor does this sequence of target values ever get revised. Whatever happens during the quarter, the *FOMC* continuously strives for equality between actual M and successive values of the predetermined target sequence. So what would seem to be its intermediate objective—to repeat, achieving equality between actual and target values of M—is in a very real sense its ultimate objective. But it goes about trying to achieve its intermediate objective in a particular way. At the beginning of each week, it determines a sequence of target values for R, its operating variable, a sequence which, like the quarterly sequence of M, never gets revised. Over the week, the *FOMC* tries, by managing its portfolio, to achieve equality between actual R and the successive values of the predetermined sequence. It thus has not only an intermediate objective but also what we might call a proximate (weekly) objective.

Unless the economic structure structure is very special, however, it is not optimal to proceed in this way, using an intermediate target variable (or an operating variable). To put the point differently, it is not optimal to use predetermined sequences of target values, sequences which, although new observations are received, never get revised. That is what we now show. We first derive what for the intermediate target variable or *FOMC* strategy is the optimal sequence of portfolio values.

The target path of M is the day 1 path of expected values, E_1M_t, $t=1, 2, \ldots, Q$, determined by the equalities $E_1Y_t=\bar{Y}$ and equations (1), (3), and (5). If actual M were always on this path and if there were no disturbances, then actual Y would always be on its target path. The *FOMC*'s intermediate objective is therefore that

$$E_TM_{T+h} = E_1M_{T+h} \tag{51}$$

be satisfied for all $T=1, \omega+1, 2\omega+1, \ldots, (s-1)\omega+1$ and $h=0, 1, \ldots, \omega-1$. The term E_TM_{T+h} is of course the expected value of M_{T+h} as of the beginning of day T, the first day of some week.

But as we have already indicated, the *FOMC* goes about ensuring that equations (51) are satisfied in a particular way. At the beginning of day T, it determines a sequence of target values for R, its operating variable, a sequence denoted by $\bar{E}_TR_{T+h}$, where $h=0, 1, \ldots, \omega-1$, which satisfies equations (51). This sequence is obtained as follows. By equations (1), (3), and (5)

$$M_t = \epsilon_0 + \epsilon_1R_t + A_\rho' a_{t-1} + A'u_{t-1} \tag{52}$$

where

$$\begin{aligned}\epsilon_0 &= \alpha_2 + \alpha_0\alpha_3\\ \epsilon_1 &= \alpha_4 + \alpha_1\alpha_3\\ A_\rho' &= (\rho_1\alpha_3, \rho_2, 0)\end{aligned}$$

and

$$A' = (\alpha_3, 1, 0)$$

Therefore,

$$E_tM_t = \epsilon_0 + \epsilon_1E_tR_t + A_\rho' E_ta_{t-1} \tag{53}$$

and

$$\begin{aligned}&E_TM_{T+h} - E_1M_{T+h}\\ &\quad= \epsilon_1(E_TR_{T+h} - E_1R_{T+h})\\ &\qquad+ A_\rho'(E_Ta_{T+h-1} - E_1a_{T+h-1})\end{aligned} \tag{54}$$

Equations (54), together with equations (51), give the sequence, so

$$\bar{E}_T R_{T+h} = E_1 R_{T+h} - \frac{A_\rho'}{\epsilon_1}(E_T a_{T+h-1} - E_1 a_{T+h-1}) \tag{55}$$

And since $E_1 R_{T+h}$ is the expected value of R_t obtained from equation (6) with $E_1 Y_{T+h}$ set equal to $\tilde{Y}$,

$$\bar{E}_T R_{T+h} = [\tilde{Y} - \alpha_0 - \rho_1 E_1 a_{T+h-1}(1) - \frac{A_\rho'}{\epsilon_1}(E_T a_{T+h-1} - E_1 a_{T+h-1})]/\alpha_1 \tag{56}$$

The *FOMC*'s proximate objective is that

$$E_{T+h} R_{T+h} = \bar{E}_T R_{T+h} \tag{57}$$

be satisfied for all $h=0, 1, \ldots, \omega-1$. The expected value of R_{T+h} as of the beginning of day $T+h$ is to equal the target value for R_{T+h}, which is the expected value as of the beginning of day T. Why this proximate objective will be clear. Along the path $\bar{E}_T R_{T+h}$, the expected value of M_{T+h} as of the beginning of day T is equal to the target value of M_{T+h}, the expected value as of the beginning of day 1.

And now to get the sequence of values for the *FOMC*'s portfolio, denoted by $\bar{P}_{T+h}$, where $h=0, 1, \ldots, \omega-1$, which is open market policy for the week. It is the sequence which satisfies equations (57). But by equations (20),

$$E_{T+h} R_{T+h} = \gamma_0 + \frac{\delta_1}{\alpha_1} P_{T+h} + \Gamma_\rho' E_{T+h} a_{T+h-1} \tag{58}$$

So, by equations (57) and equations (56), we derive an expression for $\bar{P}_{T+h}$ in equation (59) shown below.

We are finally in a position to evaluate the intermediate target variable strategy. This we do my comparing $\bar{P}_{T+h}$ and $\tilde{P}_{T+h}$, the value of the *FOMC* portfolio which minimizes expected loss. Since

$$\Delta_\rho' - \alpha_1 \Gamma_\rho' = (\rho_1, 0, 0)$$

It follows from equations (15) and (59) that

$$\bar{P}_{T+h} - \tilde{P}_{T+h} = \frac{\rho_1}{\delta_1}(E_{T+h} a_{T+h-1} - E_1 a_{T+h-1}) - \frac{\alpha_1}{\delta_1 \epsilon_1} A_\rho' (E_T a_{T+h-1} - E_1 a_{T+h-1}) \tag{60}$$

But by equation (60), $\bar{P}_{T+h} - \tilde{P}_{T+h}$ vanishes for $T=1, \omega+1, \ldots, (s-1)\omega+1$ and $h=0, 1, \ldots, \omega-1$ if, and only if, $\rho_1=\rho_2=0$. Thus, except on the first day of the quarter, the *FOMC*'s way of determining its portfolio (in open market policy) is optimal if, and only if, $\rho_1=\rho_2=0$. Yet, $\rho_1=\rho_2=0$ means that the disturbances of equations (1) and (3) are not serially correlated or, more generally, that the past influences neither the private sector's desired expenditure for newly produced goods and services nor its desired stock of demand deposits. And this, it would seem, is not what most economists believe.

There are economists (we might call them monetarists) who have, though, advocated that the *FOMC* use M as, in effect, its ultimate target variable or, what comes to the same thing, that it start off the quarter by determining a target path, $E_1 M_t$, and strive through the quarter to stay on this path. It would therefore seem worthwhile to get conditions under which it is optimal to use M rather than Y as the target variable. We do so, however, on the

$$\bar{P}_{T+h} = \frac{1}{\delta_1}(\tilde{Y} - \delta_0) - \frac{\rho_1}{\delta_1} E_1 a_{T+h-1} - \frac{\alpha_1}{\delta_1}\Gamma_\rho' E_{T+h} a_{T+h-1} - \frac{\alpha_1}{\delta_1 \epsilon_1} A_\rho' (E_T a_{T+h-1} - E_1 a_{T+h-1}) \tag{59}$$

assumption that the value of P_t is determined directly from

$$(61) \qquad E_t M_t = E_1 M_t$$

The value so determined is $\hat{P}_t$. And, by equation (35),[14]

$$(62) \qquad \hat{P}_t - \tilde{P}_t = \left(\frac{1}{\delta_1}\Delta_\rho' - \frac{\alpha_1}{\delta_1}\Gamma_\rho' - \frac{\alpha_1}{\delta_1\epsilon_1}A_\rho'\right) \cdot (E_t a_{t-1} - E_1 a_{t-1})$$

But since

$$\left(\frac{1}{\delta_1}\Delta_\rho' - \frac{\alpha_1}{\delta_1}\Gamma_\rho' - \frac{\alpha_1}{\delta_1\epsilon_1}A_\rho'\right) = \left[\rho_1\left(1 - \frac{\alpha_1\alpha_3}{\alpha_4 + \alpha_1\alpha_3}\right), -\rho_2\frac{\alpha_1}{\alpha_4 + \alpha_1\alpha_3}, 0\right]$$

It is immediate that $\hat{P}_t = \tilde{P}_t$ if, and only if, $\alpha_4, \rho_2 = 0$ or $\rho_1, \rho_2 = 0$.

Those who would have the *FOMC* use M as in effect its ultimate target variable evidently believe therefore either that the past influences neither the private sector's desired expenditures nor its desired stock of deposits or, what is more likely, that neither the past nor the rate of interest influences the private sector's desired stock of deposits. This does not seem terribly likely. But even if we accepted that the private sector's desired stock of deposits is not influenced by the past or by the rate of interest, we would not get optimality for the *FOMC* strategy. It involves the substitution of M for Y as the ultimate target variable. It also involves choosing a sequence of target values for its operating variable, R, at the beginning of each week. And that is what is not optimal, even on the assumption that the private sector's desired stock of deposits is not influenced by the past or by the rate of interest. The proof of this is easy. By equation (60), if $\alpha_4, \rho_2 = 0$ and $\rho_1 \neq 0$, then $\bar{P}_t \neq \tilde{P}_t$.

We must point out before concluding, that in evaluating the intermediate target variable or *FOMC* strategy, we have been concerned entirely with the implied value of the given instrument variable P. But $\bar{P} = \tilde{P}$ is only a necessary condition for optimality. The implied value for P could be $\bar{P}$ and still the *FOMC* strategy might not be optimal. For there is another possible instrument variable, R, which the *FOMC* could be well advised to use. Some have denied this possibility. By inequalities (16), however, $\alpha_4, \rho_2 = 0$ (or $\rho_1 = \rho_2 = 0$) does not imply that P is the better instrument variable.

IV. Conclusion

We began by setting out certain simplifying assumptions and we must now, in ending, be clear on what it means, our having made these assumptions. So far as we know, what we have provided in this paper is not the optimal strategy for open market operations but only an optimal strategy. Had we started out with different assumptions, we likely would not have come to exactly the strategy of Sections I and II. And we might not have found the intermediate target variable strategy of Section III to be generally sub-optimal. We are disposed to think, though, that we would have.[15]

Some readers may already have dismissed our conclusion about the sub-optimality of the intermediate target variable strategy (or, more particularly, the *FOMC* strategy) as being of no practical significance. In deriving it, did we not use what even we described as an unrealistic assumption—to wit, that the central

[14] It will be noted that if $h=0$, then equations (60) and (62) are the same. What this means is that, given M as the ultimate target variable, the *FOMC* strategy is optimal for the first day of the week.

[15] Unless of course we had started out by assuming serially uncorrelated residuals. (Recall our having shown that with serially uncorrelated residuals the strategy of Section III is optimal.) We have in mind the possibility of having started out by allowing for uncertainty about the values of the constants and coefficients of the economic structure.

bank knows with certainty that version of the economic structure which holds over the decision period or, as we would say, over days? Think of the *FOMC*. Its decision period is the calendar day. And can it seriously be maintained that the *FOMC* knows with certainty that version of the *U.S.* economic structure which determines, *inter alia*, daily *GNP* and daily average interest rates? For one thing, the U.S. Department of Commerce has yet to provide estimates of monthly *GNP*, to say nothing of daily *GNP*.

Yet, even if we had been confident of our ability to manage with any assumptions whatever, we would not have started off by assuming that the central bank knows nothing about that version of the economic structure which holds over the decision period, but rather that it is uncertain about constant and coefficient values. And why? Well, consider the *FOMC*'s situation. It presumably knows, although not with certainty, that version of the *U.S.* economic structure which holds over calendar quarters or which determines calendar-quarter *GNP* and, say, the quarterly average stock of money. All the various versions of any economic structure must, however, be consistent. So there is a version of the *U.S.* economic structure which holds over the calendar day and which, being implied by the version holding over the calendar quarter, the *FOMC* could come to know, although again not with certainty.[16]

We are not saying that the *FOMC* actually knows that version of the *U.S.* economic structure which determines calendar-day *GNP*, but only that by spending sufficient time and money it could. This being so, it would not have been unreasonable if we had started out by assuming that the central bank knows, if with uncertainty, the decision period version of the economic structure. At issue therefore is whether on this assumption the intermediate target variable strategy of Section III is optimal. And as we have already indicated, we are doubtful. The point is that the use of an intermediate target variable necessarily involves some waste of information which, if initial conditions matter, is valuable. And it is difficult to imagine the waste of valuable information being optimal, even for a central bank which is uncertain about the appropriate version of the economic structure constraining it.[17] We must admit, however, to having no idea how far from optimal the *FOMC*'s strategy is. Nor will we until we have determined the optimal open market strategy for a central bank which is uncertain about the version of the economic structure which holds over its decision period

APPENDIX

Deposit Stock Observation Errors

One of our information assumptions was that at the beginning of the first day of each week, the central bank gets error-free observations on the deposit stock for all the days of the week just past. We might, however, have made a more realistic assumption: that it gets only estimates for the days of the week just past and, at the same time, error-free observations for the days of the week before that. Actually, it would not have made all that much difference if we had; our optimal strategy would not have been much different. But since the *FOMC* initially gets estimates of the daily deposit stock, it is per-

[16] Quite obviously, there may be several different consistent versions of the structure which holds over the decision period. There is one version, however, of which all of these versions are special cases.

[17] We note in passing, for the benefit of those who might want to insist (in our view, quite mistakenly) on complete ignorance of the decision period version of the economic structure, that this can hardly imply use of one or several intermediate target variables. Such use necessarily involves changing the value of the instrument variable from decision period to decision period. But if ignorance is complete, there is no way, other than by guessing, of determining the appropriate new value for the instrument variable.

haps worth explaining how the introduction of observation errors changes the optimal open market strategy.

To anticipate, the central bank's expectations change with the introduction of deposit stock observation errors. It gets its expected values of, say, initial conditions exactly as it would if there were no observation errors, by using observations on all information variables and such estimates of the deposit stock as are available. But, again, its expectations are not the same as they would be if there were no errors of observation. Nor is the sequence of optimal values for the instrument variable(s); as will be recalled, expectations of initial conditions partly determine optimal policy. The central bank proceeds, however, exactly as it would if there were no observation errors; in determining its optimal instrument variable and the optimal value thereof, it uses formulae entirely analogous to those given in the text.

The estimate of the deposit stock for day t is

$$\hat{M}_t = M_t + v_t$$

where v_t is normally distributed,

$$E_t v_t = 0$$

$$E_t(v_t v_{t+h}) = \begin{cases} V_t v_t = Vv & \text{for } h = 0 \\ 0 & \text{otherwise} \end{cases}$$

and

$$E_t[v_t u_t(i)] = 0 \quad \text{for all } i$$

The central bank starts off the first day of the quarter with full information, except about the daily deposit stock. For the last week of the quarter just past, it has only estimates of the daily deposit stock. Not knowing M_0, it therefore goes back, as it were to the beginning of the day $-(\omega-1)$, the first day of the last week of the quarter just past, and calculates $a_{-\omega}$. (Since it has full information, determining these initial conditions is a simple exercise in arithmetic.) Then, using the calculated $a_{-\omega}$, observations of $Y_{-\omega+1}$ and $P_{-\omega+1}$ or $R_{-\omega+1}$ and the estimate $\hat{M}_{-\omega+1}$, it calculates the revised expectations $E^*_{-\omega+2}a_{-\omega+1}$ and $\hat{\Pi}_{-\omega+2}$. There is a generalization of equation (17) which does not require that the X's be uncorrelated and a particular version of this generalization is what the central bank uses. It proceeds day by day through the last week of the quarter just past and ends with the needed expectations $E_1^* a_0$ and $\hat{\Pi}_1$ where as can be shown

$$\hat{\Pi}_1 = \tau_1 Vv \begin{bmatrix} 0 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 1 & 1 \end{bmatrix}, \quad 0 < \tau_1 < 1$$

Having come up with $E_1^* a_0$ and $\hat{\Pi}_1$, the central bank is able to determine open market policy for the first day of the current quarter. Using $\hat{\Pi}_1$, it determines which is the better instrument variable, P or R.[18] And using $E_1^* a_0$, it determines the optimal value of its chosen instrument variable.

At the beginning of day t, where t=2, 3, . . . , ω, the central bank uses equations which are just like equations (18) and (29), except that $\hat{\Pi}_t$ appears in place of Π_t.

At the beginning of the first day of the second week, the central bank observes the daily deposit stock for the days of the last week of the previous quarter and gets estimates for the days of the first week of the current quarter. It therefore starts off the second week knowing a_0. So it is able, using the known a_0 and the estimates $\hat{M}_1, \hat{M}_2, \ldots, \hat{M}_\omega$, to revise its expectations of a_t, t=1, 2, . . . , ω and thus come to an expected value for $a_{\omega+1}$.

Because $\hat{M}_t$ is only an estimate of M_t,

$$\hat{m}_t^* = \hat{M}_t - E_t^* \hat{M}_t = m_t^* + v_t$$

It follows that

$$\hat{z}_t(1) \equiv \hat{m}_t^* - \alpha_6 v_t^* = Z_t(1) + v_t$$

and

$$\hat{z}_t(2) \equiv (\delta_3/\alpha_1)\hat{z}_t(1) + r_t^* = Z_t(2) + (\delta_3/\alpha_1)v_t$$

But then $\hat{z}_t(1)$ and $\hat{z}_t(2)$ are correlated, so with observation errors the revised expecta-

[18] It might be expected that by increasing Vv, R can be made the optimal instrument variable for day 1. And, indeed, if $\rho_2 \neq \rho_3$, that is so. If $\rho_2 = \rho_3$, however, then inequalities (16) apply unchanged.

tions of the $a_{t-1}(i)$, or of initial conditions for day t, are[19]

$$E_t^* a_{t-1}(i) = E_{t-1}^* a_{t-1}(i) + \sum_{k=1}^{2} \hat{\phi}_t(i,k)\hat{z}_{t-1}(k)$$

where

$$\begin{bmatrix} \hat{\phi}_t^*(i,1) \\ \hat{\phi}_t^*(i,2) \end{bmatrix} = \left[E_{t-1}^*(\hat{z}_{t-1}\hat{z}_{t-1}')\right]^{-1} C_{t-1}^*\left[\hat{z}_{t-1}, a_{t-1}(i)\right]$$

and

$$\hat{z}_{t-1}' = \left[\hat{z}_{t-1}(1), \hat{z}_{t-1}(2)\right]$$

Finally,[20]

$$\hat{\Pi}_t^*(i,j) = \rho_i\rho_j \Pi_{t-1}^*(i,j) + E[u(i)u(j)] - \hat{\phi}_t^*(i)' E_{t-1}^*(\hat{z}_{t-1}\hat{z}_{t-1}')\hat{\phi}_t^*(j)$$

[19] These equations are substitutes for equations (42).

[20] These equations substitute for equations (44). Note that $\hat{\Pi}_1^* = 0$.

A Dynamic Theory of Comparative Advantage

By ROGER W. KLEIN*

The purpose of this paper is to explain two aspects of international trade in the post-World War II period. First, *U.S.* firms, operating within the United States, are often the first to innovate, develop, and produce new products. Second, the *U.S.* advantage in producing a new product often eventually shifts to another country, implying that the product is produced by either a foreign firm or a foreign subsidiary of a *U.S.* firm.[1] By explaining why and when *U.S.* firms establish foreign subsidiaries, this paper therefore attempts to explain why multi-national *U.S.* firms are formed.

A dynamic theory of comparative advantage, which helps explain the multinational firm, is formulated in Section I. It differs from previous formulations by recognizing that firms engage in Research and Development (*R&D*) to learn about a product's production process. By incorporating this learning activity into the traditional production function and specifying its dynamic properties, a dynamic theory of comparative advantage will be developed. Section II argues that this theory applies to the United States, and Section III derives a test of this theory. In Section IV, in addition to discussing the results of this test, the theory developed here will be compared with alternative explanations of the behavior described above.

I. A Dynamic Theory of Comparative Advantage

The Importance of Learning

One can distinguish two sources of a country's comparative advantage in producing a new product. First, a country might derive its advantage from employing learning factors (scientists and engineers) to learn about and improve the product's production process.[2] Second, given that the production process is completely known, a country might have an advantage in employing capital and labor to produce it. For reasons which will become apparent below, denote the former as the learning advantage and the latter as the static advantage. Then, in a two-country world, assume country I has a learning advantage while country II has a static advantage in producing commodity *a*. If the learning advantage dominates the static advantage, country I will have a comparative advantage in *a*. However, if country I's learning advantage declines over time, as either opportunities for additional learning are exhausted or as foreign countries learn about *a*'s production process, comparative advantage in *a* may shift to country II. This argument, therefore, suggests that one can formulate a dynamic theory of comparative advantage by formalizing the learning activity.

* Assistant professor of economics, Purdue University. This paper was adapted from my Ph.D. thesis, written at Yale under Tibor Scitovsky, David Grether, and John McGowan. I am very grateful for their helpful comments and suggestions. I am also very much indebted to Henry Grabowsky for supplying data on *R&D* expenditures of pharmaceutical firms and to Paul de Haen for supplying data on new products. Burton Klein and John Carlson also provided helpful comments.

[1] See the Department of Commerce.

[2] Since many aspects of the production process for a new product are unknown, firms allocate resources (scientists and engineers) to learn about the product's production process.

Assumptions

Assume that all firms are perfectly competitive and that firm i has the following production function for a specific commodity:

$$q_i = S_i(Z) \cdot G_i(K, L)$$
$$Z \equiv (z_1 \ldots, z_n)$$

S_i is firm i's knowledge function, which depends on a vector of cumulative variables. When a distinction is important, i will be denoted IN for the innovator (assumed to be a domestic firm), d for domestic firms, and f for foreign firms. Then assume:

(a) $\partial S_i/\partial z_j > 0; \quad \partial^2/S_i/\partial z_j^2 < 0$

The marginal products of learning factors are positive and diminishing.

(b) $\text{Maximum}\,(S_i) = \underset{Z\to\infty}{\text{Limit}}\,(S_i) = 1$

There is an upper, asymptotic bound on the knowledge function for a specific product.[3]

(c) $S_d(\overline{Z}) > S_f(\overline{Z}) > 0$

For a fixed level of learning factors, $\overline{Z}$, all domestic firms have a learning advantage over foreign firms.

(d) Domestic firms must produce in the domestic country to realize the advantage stated in (c).

(e) The following notation depicts long-run cost functions,[4] exclusive of $R\&D$ expenditures, at time t for the ith firm that entered the market at time s:

AC^i_{st} = Average Cost

$NLAC^i_{st}$ = Average Cost when learning ceases, i.e., when $S_i \approx 1$

Assume:

i) min $(NLAC^f_{st})$ < min $(NLAC^d_{st})$, for all s, t. Foreign firms (f) have an advantage in terms of K and L (the static advantage). For simplicity, assume these average cost functions are constant.

ii) In nominal terms, the domestic learning advantage (c) initially is sufficiently larger than the foreign static advantage to imply:

$$\min\,(AC^d_{st}) < \min\,(AC^f_{st}),$$
$$\text{for s} \leq \text{t}, \quad \text{and} \quad \text{t} < \text{v}$$

While the learning advantage dominates the static advantage (until time v), domestic firms can produce the commodity at a lower minimum average cost than foreign firms.

(f) For simplicity, assume:

$$S_i(z_1, \ldots, z_m) = S_{i1}(z_1) \cdot S_{i2})\,(z_2) \ldots S_{im}(z_m)$$

(g) All countries have identical preference maps and either identical incomes or homothetic preference maps. To emphasize the dynamics of learning, this assumption is made to guarantee that demand factors do not determine comparative advantage.

The second portion of the production function, $G_i(K, L)$, will be termed the static production function; it is the production function when the stock of knowledge ceases to increase ($S_i \approx 1$) and depends on capital, K, and labor, L. In addition to the properties usually attributed to production functions, assume G exhibits constant returns to scale and is the same for all countries.

Formulation of the Theory

Let a particular firm have the following production function at time t for a given product, a:

[3] When $S \approx 1$, $G_i(K, L)$ becomes the production function. If K and L were immobile among countries, comparative advantage would now be determined by Heckscher-Ohlin conditions. Indeed, one could describe a Heckscher-Ohlin world as one in which all factors are immobile and the stock of knowledge is constant.

[4] These are long-run cost functions in the sense that captial, K, and production labor, L_p, are completely variable. Management, L_m, is assumed to be fixed over the firm's long-run decision horizon. These cost curves will then be U-shaped.

$$q_t = S(Q_{t-1}, RD_{t-1}) \cdot G(K_t, L_t) \text{ where:}$$

$$Q_{t-1} \equiv \text{cumulative output} \equiv \sum_{k=1}^{t-1} q_k$$

$$RD_{t-1} \equiv \text{cumulative, real } R\&D \equiv \sum_{k=1}^{t-1} rd_k$$

Q_{t-1} reflects "learning by doing" and is assumed to be exogenous (see Kenneth Arrow, pp. 165–73), while RD_{t-1} reflects *R&D*-learning (allocating resources to learn about a product's production process) and is assumed to be endogenous.

Since rd_t is an endogenous variable affecting all future production levels, a profit maximizing firm chooses rd_t, q_t, K_t, and L_t to maximize its discounted profit stream. This behavior can be simplified because these values of q_t, K_t, and L_t also maximize period t's profits. Moreover, firms can employ research factors to learn about a commodity's production process without producing it commercially.[5] Consequently, firms can separate learning decisions from production decisions.

This separation implies that firms only consider period t's profits when they decide to begin or cease production. These decisions, therefore, can and will be formulated in terms of cost curves. A firm begins or ceases production according to whether price exceeds or is less than its minimum average cost (excluding *R&D* expenditures).

In addition to the firm behavior outlined above, assume the innovator (a domestic firm) maintains a monopoly position for b periods, i.e., barriers to entry disappear after period b. When the innovator loses his monopoly position, let the number of entering firms be sufficiently large that price is taken as given. Then, prior to period b, the innovator produces in the domestic country to exploit his learning advantage (Assumptions c, d, and e) and maximizes profits by equating marginal revenue to marginal cost.

In period b+1, due to their learning advantage (Assumptions c, d, and e), only domestic firms enter the market. All firms equate marginal cost to price and entrance ceases when price equals the marginal firm's minimum average cost. Since all firms entering in this period are marginal firms,[6] price is determined by their minimum average cost. Measuring profits exclusive of *R&D* expenditures, the firm that first entered the market earns a positive profit, while all other domestic firms' profits are zero. Subsequent periods can be described analogously; intramarginal firms earn positive profits, while marginal firms (those just entering the market) earn a zero profit.

Eventually, since the knowledge function is bounded and the foreign country has a static advantage, domestic firms will begin to shift their production to the foreign country. In other words, eventually the advantage of producing in the foreign country will outweigh cost reductions obtained by remaining in the domestic country to exploit the learning advantage. If the United States is the domestic country, therefore, this formulation would explain why comparative advantage often eventually shifts away from the United States. This in turn would explain why *U.S.* firms establish foreign subsidiaries.

II. The *U.S.* Learning Advantage

To identify the United States with the domestic country and apply the theory formulated above, one must show that *U.S.* firms have a learning advantage, and

[5] Commercial production begins when a firm has some knowledge of its product's production process and knows that there is a demand for its product. Prior to this, firms may and probably will engage in pilot-plant production (exploratory, small-scale production).

[6] Because of cumulative variables in knowledge functions, marginal domestic firms are those that have most recently entered the market.

that this advantage can be realized only by producing in the United States. The *U.S.* learning advantage results from the high marginal products of learning resources (scientists and engineers) in *U.S.* firms relative to other countries.[7] First, scientists and engineers in *U.S.* industry are evenly distributed between production (37 percent) and *R&D* (35 percent), with a significant percentage in management and administration (8 percent).[8] Comparable data for other countries have been found for Greece, the United Kingdom, and Canada. With the exception of Canada,[9] the distribution of scientists and engineers is skewed in these foreign countries relative to the United States. In Greece, 91 percent of the scientists and engineers are engaged in production,[10] while in the United Kingdom, the ratio of research to production scientists is five times that in the United States.[11]

Additional country data are necessary to determine to what extent Canada is an exception in having an even distribution of scientists and engineers throughout all employment levels of Canadian firms. One can conclude that the distribution of scientists and engineers throughout all employment levels in *U.S.* firms has contributed to their high marginal product in three ways:[12] by facilitating the ability of plant managers to transform *R&D* output into production; by increasing the ability of executives to evaluate research activity; and by increasing communication within the firm.

For instance, according to Robert Kornhauser:

> . . . the chairman of the board at American Brake Shoe Company asserts that the research department might have failed many times to get a new product into manufacture if there had not been men with an engineering background in management. [p. 176]

The above discussion dealt with integrating research personnel into the firm to increase the effective utilization of research Second, and equally important, is integrating management into research departments. A study of 405 research laboratories in the United States found that the research director usually had scientific training (Kornhauser, p. 176). In an intercountry comparison of *R&D*, the Organization for European Economic Cooperation (*OEEC*), stresses the importance of such training:

> If applied research programmes are to be effective and research organizations make their full contribution, they must be soundly and well administered. More attention should be given, as in the United States, to the training of research directors combining the qualities of the scientist and the manager. [p. 70]

Third, the marginal product of scientists and engineers is also higher in the United States because of the close cooperation between the university, government, and industry. The *OEEC* study (p. 70), found that this cooperation was greater in the United States than in Europe.

Finally, *U.S.* firms provide a very favorable environment for research and development. Industrial laboratories have replaced amateur inventors and unplanned individual innovation everywhere, creating potential conflicts within the firm between scientists and management. Kornhauser has analyzed these conflicts and has shown that *U.S.* firms have been very successful in resolving them, thereby creating a favorable environment for *R&D* in *U.S.* industry. A lack of data prohibits intercountry comparisons, but of eleven countries studied by the Organization for European Cooperation and Development

[7] Scientists and engineers are engaged not only in developing and improving production processes but also in developing new products. Consequently, if their marginal product is higher in *U.S.* firms, these firms must have an advantage in innovating in addition to learning.

[8] See *OECD*, p. 174. The importance of this even distribution is shown below.

[9] *OECD*, p. 152.

[10] See *OECD*, p. 152.

[11] See Merton J. Peck, pp. 454–86.

[12] See Peck, pp. 454–86.

(*OECD*) in 1963, the United States had the highest percentage (74 percent) of scientists and engineers in industry (see *OECD*, p. 117). This suggests that *U.S.* industry may provide a more favorable environment for these learning factors.

To apply the theory in Section I to the United States, one must show not only that *U.S.* firms have a learning advantage, but also that this advantage is limited to the geographical confines of the United States. Preceding arguments have only shown that *U.S.* firms have a learning advantage. One can show, however, that this advantage is best realized by producing in this country.

First, excellent communication between the university, government, and industry was listed as an important factor above, and this is clearly confined to the United States. Second, most of the *R&D* facilities of *U.S.* firms are located in this country, which is due partly to the excellent communication just mentioned. Third, the bulk of existing production facilities of *U.S.* firms is located in this country. Many innovations consist of modifications and improvements of existing products and development of related products. Existing production facilities, therefore, are both suitable and useful in the early production stages. This latter factor diminishes in importance as *U.S.* firms establish production facilities abroad. Nevertheless, it is evident from this discussion that the *U.S.* learning advantage is currently confined to this country.

III. Testing the Theory

The Model

To test this theory, a model has been formulated to explain the behavior of a cross-section of *U.S.* firms over time. The model contains four equations that explain applied research expenditures, new product innovation, research expenditures for process improvement, and the difference between foreign subsidiary sales and domestic sales. Since data have been found only to estimate the last equation, which tests the theory, only this equation will be discussed and estimated.[13]

The microtheory formulated in Section I requires one to specify this equation for an individual commodity:

$$
\begin{aligned}
& FS_{ijt} - DS_{ijt} \\
(1) \quad & = \overset{1}{c}_{ij}\cdot(FM_j) + h\cdot(F_{ij} - \hat{S}_{ij}(RD_{ijt-1})) \\
& \quad \cdot TS_{ijt-1} + \overset{2}{c}_{ij}\cdot(M_j) + u_{ijt}
\end{aligned}
$$

In equation (1), subscripts i, j, and t refer to firm i, product j, and time t. The variable FS_{ijt} denotes foreign subsidiary sales, DS_{ijt} denotes domestic sales. The variable FM_j is a dummy for product j that equals one in the first year that product j is marketed and zero otherwise. The variable F_{ij}, which is less than one, is the value of the knowledge function, S, when domestic firms switch production to the foreign country. In other words, it is the value of S when the foreign static advantage outweighs the domestic learning advantage. The function $\hat{S}_{ij}(RD_{ijt-1})$ is firm i's estimate of its knowledge function for product j.[14] The variable TS_{ijt-1} denotes total sales (domestic plus foreign). The variable M_j is a dummy for product j that equals zero in the first that year product j is marketed and one otherwise. The variable u_{ijt} is the disturbance term, and c_{ij}^1, c_{ij}^2, and h are negative constants.

Because of the nature of the dummy variables, FM_j and M_j, and except for the disturbance, c_i^1 is the only nonzero term in

[13] Even though only one equation will be estimated, the estimation procedure will take into account that it is part of a simultaneous equation model. For a complete discussion of equations in the model *not* discussed here, see my Ph.D. dissertation.

[14] Assuming firms attribute all learning to *R&D* (learning by doing is exogenous and relatively unimportant), $\hat{S}_{ij}$ depends only on cumulative *R&D*. Further assuming that firms decide in period t−1 whether or not to switch production locations, $\hat{S}_{ij}$ depends on RD_{ijt-1}.

the equation when product j is first produced. Similarly, c^2_{ij} is the only nonzero term when $\hat{S}_{ij}=F_{ij}$. Consequently, $-c^1_{ij}$ equals domestic sales when product j is first produced, while $-c^2_{ij}$ is the level of domestic sales immediately prior to the establishment of a foreign subsidiary.

In other years, the explanatory term is $h\cdot(F_{ij}-\hat{S}_{ij})$, which is directly related to the theory in Section I. Since h is negative, domestic production expands when domestic firms conclude that their opportunities for learning are sufficiently large ($\hat{S}_{ij}<F_{ij}$) to justify producing all of product j in the domestic country. When these firms believe that additional opportunities for learning are small ($\hat{S}_{ij}>F_{ij}$), they begin to shift production of product j to the foreign country. When this occurs, foreign subsidiary sales expand.[15]

The size of period t's domestic or foreign subsidiary sales depends not only on the knowledge function, but also on consumers' acceptance of the product. The term $F_{ij}-\hat{S}_{ij}(RD_{ijt-1})$ is multiplied, therefore, by the firm's sales of product j in period $t-1$.[16]

To test this equation, since data were unavailable for individual products, it was aggregated over all products:[17]

$$(FS_{it}-DS_{it}) = h\cdot\sum_{j=1}^{P_{it}}[(F_{ij}-\hat{S}_{ij}(RD_{ijt-1}))\cdot TS_{ijt-1}] + \sum_{j=1}^{N_{it}}(c^1_{ij}) + \sum_{j=1}^{(P_{it}-N_{it})}(c^2_{ij}) + \sum_{j=1}^{P_{it}} u_{ijt} \tag{2}$$

In equation (2) P_{it} is the number of products produced and N_{it} the number introduced by firm i at time t. Because data have not been obtained for most of the variables in equation (2), the following assumptions are made to transform (2) into a form in which it can be estimated:

(i) In choosing research factors, re_{ijt}, assuming the shortest horizon possible yields:[18]

$$re_{ijt} = \hat{E}_{st}\cdot\hat{T}S_{ijt+1}\cdot d(1) + e_{ijt}$$

where $\hat{E}_s$, denotes the firm's estimate of E_s, the elasticity of learning with respect to learning factors (re_{ijt}); $\hat{T}S_{ijt+1}$ denotes the firm's estimate (made at time t) of total sales at time t+1; $d(1)=1/(1+r)$ is a constant discount factor; e_{ijt} is a disturbance term. Further assume:

$$\hat{E}_{st} = a(1-\hat{S}_{ij}(RD_{ijt})), \quad a>0\text{[19]}$$

$$\hat{T}S_{ijt+1} = (1+g)TS_{ijt}, \quad g>0\text{[20]}$$

[15] One might prefer to employ real rather than nominal sales data. In the pharmaceutical industry, which will be used to test the theory, prices have remained relatively stable. Consequently, nominal sales are approximately equal to real sales.

[16] This is particularly important in the pharmaceutical industry, because doctors and other purchasing agents do not have time to evaluate each of the many drugs introduced each year; to a large extent they rely on information distributed by drug firms. That firm, *ceteris paribus*, which has been most successful in distributing such information will have the greater sales in period t. Let TS_{ijt-1} measure the success with which this information has been disseminated.

[17] This equation was derived to explain shifts in comparative advantage. Since production costs are low in the pharmaceutical industrial, tariffs and/or tax differentials may be important in determining the location of foreign subsidiaries of *U.S.* firms. In this event comparative advantage, as traditionally defined, would not necessarily shift to the foreign country. Nevertheless, the theory formulated here still applies; *U.S.* firms establish foreign subsidiaries when tariff and/or tax considerations dominate future opportunities for learning.

[18] Since new-product demand is uncertain, a firm may adopt the shortest planning horizon possible.

[19] This specification states that the elasticity, E, depends linearly on the distance of S from its upper bound; it is largest when learning first begins and subsequently declines. This corresponds to the assumption that learning consists initially of major breakthroughs, which are followed by refinements. When learning ceases ($S\approx 1$), E is zero as one would intuitively expect. It is interesting to note that those who argue that *R&D* expenditures bear a constant relation to sales may be implicitly assuming that this elasticity is constant.

[20] Since period t+1's sales of product j are unknown at time t, the firm must estimate them. One could argue that estimated sales in period t+1 are a distributed lag function of past sales. This possibility was not explored because of the small data sample. Instead, it was simply assumed that sales are expected to grow by some constant proportion, g.

(ii) A firm's total sales depend on prices, the "newness of its product," etc., but not on the switching point F_{ij}. Consequently, F_{ij} and TS_{ijt-1} are uncorrelated, implying that

$$\left[\sum_j F_{ij}/P_{it}\right]\cdot \sum_j TS_{ijt} \equiv \overline{F}_{it}\cdot TS_{it-1}$$

is an unbiased estimate of

$$\sum_j F_{ij}\cdot TS_{ijt-1}$$

Assuming $\overline{F}_{it}\approx F$, i.e., F_{it} is approximately constant:

$$\sum_j F_{ij}\cdot TS_{ijt-1} \approx F\cdot TS_{it-1}$$

(iii) Define $\bar{c}^1_{it}$ and $\bar{c}^2_{it}$ as:

$$\bar{c}^1_{it} \equiv \sum_{j=1}^{N_{it}} (c^1_{ij}/N_{it});$$

$$\bar{c}^2_{it} \equiv \sum_{j=1}^{(P_{it}-N_{it})} (c^2_{ij}/(P_{it}-N_{it}))$$

Assuming $\bar{c}^1_{it}\approx c^1$ and $\bar{c}^2_{it}\approx c^2$, i.e., these means are approximately constant, yields:

$$\sum_j c^1_{ij} \approx c^1\cdot N_{it};\quad \sum_j c^2_{ij} \approx c^2\cdot(P_{it}-N_{it})$$

Then, substituting (i), (ii), and (iii) into equation (2) yields an estimatable equation:

$$(3)\quad \begin{aligned}(FS_t - DS_{it}) &= b_1 re_{it-1} + b_2 TS_{ijt-1}\\ &+ b_3 N_{it} + b_4(P_{it}-N_{it}) + w_{it}\end{aligned}$$

In equation (3):

$b_1 \equiv h/(a\cdot d(1)) < 0$ since $h<0$ and $a\cdot d(1)>0$

$b_2 \equiv -h(1-F) > 0$ since $h<0$ and $F<1$

$b_3 \equiv c^1,\ c^1<0;\quad b_4\equiv c^2,\ c^2<0$

$$w_{it} = \sum_j u_{itj} + \sum_j v_{ijt-1},$$

$$v_{ijt} \equiv [-1/(a\cdot d(1))]e_{ijt}$$

and

$$j = 1, \ldots, P_{it}$$

The Data

Complete data were obtained for three nonproprietary drug firms for the period 1962–68 and for an additional firm for the period 1964–68. The sample of twenty-six observations was obtained by pooling a cross-section of these firms.

A National Science Foundation questionnaire (*NSF* #1) was used to determine domestic sales. These were defined to be sales of *U.S.* firms located in the United States. Total sales were obtained from the Compustat Tape (Standard Statistics Co., Inc.). Foreign subsidiary sales of each drug firm were then derived by subtracting domestic sales from total sales.

R&D data for these firms were also obtained from the *NSF* questionnaire. Ideally one would want *R&D* expenditures allocated to process improvement. The *NSF* questionnaire classified *R&D* expenditures as basic, applied, or development. The latter appears to correspond closely to expenditures for process improvement. The National Science Foundation has defined these expenditures to include:

> The design and operation of pilot plants or semiworks plants so long as the principal purposes are to obtain experience and to compile engineering and other data to be used in evaluating hypotheses, in writing product formulas, or in establishing finished product specifications, in designing special equipment and structures required by a process and in preparing operating instructions or manuals. [#2(1968), p. 137]

Unfortunately, in addition to process improvement, these data include expenditures for "writing product formulas" and "establishing finished product specifications." In other words, expenditures for testing new drugs are included in this category. Furthermore, due to more re-

strictive drug legislation, which became effective in 1963, these testing costs have increased in the sample period.[21]

Although data on testing costs were unavailable, they can be estimated by making several assumptions. Paul de Haen classifies New Drugs as new single ingredients, duplicate single ingredients, combination products, and new dosage forms. Most testing costs are undoubtedly incurred for the first of these, new single ingredients. Assume further that the cost per product changes only in response to changes in drug legislation. Denote α_{ij}^1 and α_{ij}^2 as the costs of testing new drugs in the periods 1960–62 and 1963–68, respectively. Then, since α_{ij}^1 and α_{ij}^2 are fixed costs, re_{it}, firm i's expenditure for process improvement at time t, is given by equation (4):

$$re_{it} = re'_{it} - [\bar{\alpha}^1_{it}\cdot(d_1\cdot NS_{it}) + \bar{\alpha}^2_{it}\cdot(d_2\cdot NS_{it})] \tag{4}$$

In equation (4) re'_{it} is firm i's development expenditures, defined according to the *NSF* definition.

$$\bar{\alpha}^1_{it} \equiv \sum_j \{\alpha^1_{ij}/N_{it}\}; \quad \bar{\alpha}^2_{it} \equiv \sum_j \{\alpha^2_{ij}/N_{it}\}$$

d_1 and d_2 are dummy variables corresponding to the periods 1960–62 and 1963–68, respectively. The term NS_{it} denotes the number of new single ingredients firm i introduced at time t.[22] Assume that $\bar{\alpha}^1_{it}$ and $\bar{\alpha}^2_{it}$ are constant, i.e., $\bar{\alpha}^1_{it}=\bar{\alpha}^1$ and $\bar{\alpha}^2_{it}=\bar{\alpha}^2$. Then, substituting equation (4) into (3), and letting $b_5\equiv -\bar{\alpha}^1\cdot b_1$ and $b_6\equiv -\bar{\alpha}^2\cdot b_1$, yields equation (5) which will be estimated:

$$\begin{aligned}(FS_{it} - DS_{it}) &= b_1 re'_{it-1} + b_2 TS_{it-1} + b_3 N_{it} \\ &\quad + b_4(P_{it} - N_{it}) + b_5(d_1 NS_{it-1}) \\ &\quad + b_6(d_2 NS_{it-1}) + w_{it}\end{aligned} \tag{5}$$

Additional data on applied research expenditures on the industry level were also obtained from *NSF* (#2). This variable does not appear in equation (5), but is one of the exogenous variables in the model that will be used to estimate it. Finally, the number of drugs produced and introduced by each firm, each year, was obtained from Medical Economics, Inc., *Physicians' Desk Reference to Pharmaceutical Specialties and Biologicals.*

The Estimation Method

To estimate (5), note that the disturbance term, w_{it}, equals

$$\sum_{j=1}^{P_{it}} u_{ijt} + \sum_{j=1}^{P_{it}} v_{ijt-1}$$

Assume that each term can be decomposed as follows:

$$u_{ij} \equiv \overset{I}{u}_{ij} + \overset{II}{u}_{ijt};\ v_{ijt} \equiv \overset{I}{v}_{ij} - \overset{II}{v}_{ijt}$$

where u^I_{ij} and v^I_{ij} are time-invariant firm and/or product effects.[23] Further assume that u^I_{ij}, u^{II}_{ijt}, v^I_{ij}, and v^{II}_{ijt} are mutually independent and that u^{II}_{ijt} and v^{III}_{ijt} are serially uncorrelated. Then the variance-covariance matrix of the disturbance, Ω, is block-diagonal. A typical element of block 1, σ_{ij}, would be:[24]

i) $P_{1j}\cdot\sigma^2$ if i=j, where P_{1j} is the number of products firm 1 produces at time j; $\sigma^2\equiv$variance of w_{it}.

[21] This legislation consists of the Kefauver-Harris Drug Amendments and Investigational Drug Regulations.

[22] See de Haen (parts II and IV). I would like to thank him for supplying these data.

[23] This is similar to Pietro Balestra and Marc Nerlove's formulation, pp. 585–612. The disturbance is specified in this manner first because preliminary results indicate that autocorrelation probably exists. Second, it seems likely that there are differences among firms or products that are captured in the disturbance term.

[24] This specification implicitly assumes that for a new product there is at least a one-period lag between research expenditures for process improvement and the new product's introduction.

ii) $C_I^{ij} \cdot \sigma_I^2$ if $i \neq j$, where C_I^{ij} is the number of products produced in period i that were also produced in period j by firm 1; $\sigma_I^2 \equiv$ variance of $u_{ij}^I + v_{ij}^I$.

The assumptions above imply that Ω is not of the form $\sigma^2 \cdot I$. Moreover, TS_{it-1} and re_{it-1}^i are correlated with the disturbance. To estimate (5), therefore, a combination of Generalized-Least Squares (*GLS*) and Instrumental Variable (*IV*) estimation procedures were employed.[25]

IV: Conclusions

Estimation Results

The estimation results are shown in Table 1 for equation (5). Since $\sigma^2 \equiv \sigma_I^2 + \sigma_{II}^2$ and σ^2, σ_I^2, and σ_{II}^2 are all positive, $0 < \sigma_I^2/\sigma^2 \leq 1$. Since σ_I^2 refers to time invariant effects, they are present if σ_I^2/σ^2 equals one and absent if it equals zero. Since the estimate of this ratio was .83, these effects are probably present.

TABLE 1—ESTIMATION RESULTS[a]

b	Expected Sign	Estimate of b: $\hat{b}$	Standard Deviation	t-Statistic	F	σ_I^2/σ^2
b_1	−	−.0168*	.0017	−9.878		
b_2	+	.2005*	.0674	2.972		
b_3	−	1.3352	1.3221	1.010	9.18	.83
b_4	−	−.3578***	.2210	−1.619		
b_5	+	−13.2723	29.3280	.452		
b_6	+	8.9046**	4.9689	1.792		

[a] *, **, and *** indicate a 1, 5, or a 10 percent significance level in a one-tail test.

An F-ratio was computed to test the null hypothesis that all of the coefficients equal zero.[26] Since this ratio equals 9.18, the null hypothesis was rejected at the 1 percent level, implying that a significant relation exists between dependent and independent variables.

Except for $\hat{b}_3$ and $\hat{b}_5$, which were insignificantly different from zero, all coefficients had the expected sign. Since $-b_3$ equals the initial level of domestic sales, $\hat{b}_3$ should have been negative, but was positive. This may be due to misspecifying b_3, which was assumed to be constant and equal for all firms. These assumptions are questionable, but data did not permit an alternative specification.

Fourth, since $-b_5/b_1$ equals the average level of expenditures for testing a new drug from 1960 to 1962 and b_1 is negative, $\hat{b}_5$ should have been positive, but was negative. This unsatisfactory estimate of b_5 might indicate that development expenditures were inadequately corrected for new product testing costs.[27]

Finally, all other coefficients were significantly different from zero and had the expected sign. The estimates of $\hat{b}_1$ and $\hat{b}_2$ are of particular importance; they are the most significant estimates (they have the highest t-statistics) and are directly related to the theory in Section I. Since b_1 equals $h/(a \cdot d(1))$ and b_2 equals $-h \cdot (1-F)$, a negative value for $\hat{b}_1(a \cdot d(1)) > 0$ and a positive value for b_2 $(F<1)$ both imply that h is negative. But, h is the coefficient of the term $((F_{ij} - S_{ij}(RD_{ijt-1}))$.

[25] Write equation (5) as:

$$Y = XB + W \tag{5a}$$

Let T be a matrix such that $T'T = \Omega^{-1}$. Then, multiplying (5a) by T yields:

$$(TY) = (TX)B + (TW) \tag{5b}$$

Since the variance-covariance matrix of TW is of the form $\sigma^2 \cdot I$, it seems reasonable to apply instrumental variables to (5b). Instruments for TS_{it-1} and re_{it-1}^i were chosen by regressing these variables on all of the model's exogenous variables in the model (see my doctoral dissertation for a discussion of model's equations and exogenous variables). Letting Z be a matrix of instruments, TZ is the matrix of transformed instruments. Then, multiplying (5b) by $(TZ)'$ and setting $(TZ)'(TW)$ equal to zero, one can solve for $\hat{B}$, the *GLS-IV* estimate of B:

$$\hat{B} = (Z'\hat{\Omega}^{-1}X)^{-1}Z'\hat{\Omega}^{-1}Y$$

[26] $$F = \frac{[Y'\Omega^{-1}Y - (Y - X\hat{B})'\Omega^{-1}(Y - X\hat{B})]/6}{(Y - X\hat{B})'\hat{\Omega}^{-1}(Y - X\hat{B})/20},$$

distributed $F(6, 20)$.

[27] Since d_1 was nonzero in only two years of the sample, there were only a few observations on $(d_1 \cdot NS_{it-1})$. This could explain the low t-statistic for b_6.

Consequently, a negative value for h means that foreign subsidiary sales increase as opportunities for additional learning by *U.S.* pharmaceutical firms decline. This accords fully with what the theory of Section I would predict.

Limitations of Study

The sample size (twenty-six observations) limited the manner in which the theory was tested. Aside from questionable large-sample properties of the estimates, several interesting hypotheses could not be tested. For example, the speed with which *U.S.* firms locate abroad, the size of testing costs, and the initial and maximum level of domestic sales may vary among firms. In other words, the equation tested may be different for each firm. To test this hypothesis, however, one would have to estimate this equation for each firm. Since there were at most seven observations per firm, this was not feasible.

Another limitation was imposed by the lack of data on *U.S.* foreign subsidiary sales in each country. Had country data been available, one could have examined the special characteristics of each country (or group of countries in the case of the Common Market).

A third limitation was imposed by the lack of data on research expenditures for process improvement by pharmaceutical firms. As stated in Section III, these were estimated by subtracting an estimate of new product testing costs from development expenditures.

Finally, because individual product data were unavailable for all variables, it was difficult to interpret the estimation results. The theory formulated here pertains to an individual product, implying that the equation developed to test the theory should also refer to an individual product. Such an equation was formulated, but had to be aggregated because individual product data were unavailable. Unfortunately, because of the aggregation, each of the b_i in this equation is really the composite of several coefficients. For example, $b_1 \equiv [h/(a \cdot d(1))]$. Consequently, it was only possible to infer signs rather than actual values of certain key coefficients (i.e., h).

Conclusions

The theory formulated in Section I differs from previous formulations by recognizing the role of research and development. To a large extent firms allocate *R&D* to learn about their production processes, the cumulative effects of which are formalized in a knowledge function.

A simple formulation of this function enables one to show both why a new product is often first developed and produced in the United States, and why this country often loses its initial advantage over time. Product cycle theories also attempt to explain this behavior.[28] Such theories have made important contributions to trade theory, but exhibit several deficiencies. First, they often claim that firms produce initially in this country to minimize demand uncertainties; but this only explains why a new product is marketed, not why it is produced in this country. The theory developed here is based on supply uncertainties. As shown in Section II, this enables one to explain why new products are often produced in the United States.

Second, many product cycle theories attempt to explain shifts in comparative advantage away from the United States in terms of "technology stabilization." The knowledge function both clarifies and explains this process. A "stable technology" is one in which the stock of knowledge has become constant, because the marginal

[28] Product cycle theories were developed by Gary Hufbauer, pp. 1–165; Seev Hirsch (1965), pp. 92–97, (1967), pp. 1–133; William Gruber, Dileep Mehta, and Raymond Vernon, pp. 10–37; Michael Posner, pp. 232–41; Louis Wells, Jr., pp. 152–62; and Vernon, pp. 190–207.

product of cumulative *R&D* approaches zero. Note that comparative advantage need not shift when the stock of knowledge becomes constant, but rather when the foreign static advantage dominates the *U.S.* learning advantage.

Third, with little explanation, product cycle theories often claim that a low wage country has the static advantage described above. In other words, comparative advantage eventually shifts to such a country. This can now be explained by making three assumptions. First, investment by *U.S.* firms in foreign subsidiaries suggests that capital is mobile. Second, as argued in Section II, *R&D* is relatively immobile. Third, assume that labor is also relatively immobile. Then, since capital mobility implies that inter-country factor payments to capital converge, *R&D* and labor are the main factors in determining comparative advantage. Early in the production process, when learning is important, the *U.S.* has a comparative advantage in producing a new product. When learning becomes less important, it is then not surprising that comparative advantage should shift to a low wage country.

In conclusion, this theory argues that the dynamics of comparative advantage are due to learning. It differs from previous formulations, because it is based on those supply conditions essential to developing the production process for a new product.[29]

[29] This formulation pertains to a single, new commodity. In a multi-commodity world, one would expect the country with a learning advantage to continually shift its production to new commodities, because its greatest advantage will always be early in the learning process. If the United States has a learning advantage, then it probably has a comparative advantage in producing new products, which would imply that *U.S.* exports have a high *R&D* content. This is precisely the case, for the five industries representing only 39 percent of total *U.S.* sales account for: 1) 72 percent of *U.S.* exports; 2) 89 percent of *U.S.* research and development expenditures. (See Gruber, Mehta, and Vernon, pp. 22–23.)

A True Price Index When The Consumer Saves

By MALCOLM GALATIN*

The conventional economic theory of price or cost of living index numbers defines a true price index (*TPI*) as the ratio of two volumes of expenditure which are the minimum needed by a consumer to attain a reference level of utility in two price situations. When the two price situations are designated 0 and 1, respectively,[1] the reference level of utility is generally chosen to be that attained by the consumer in situation 0 or in situation 1. Once these *TPI*s have been defined, they may be related to measurable price indexes, and we have the well-known results that when the reference level of utility is that attained in period 1, the Paasche price index is a lower bound of a *TPI*, and when the reference level of utility is that attained in period 0, the Laspeyres' price index is an upper bound to a *TPI*.[2]

If the consumer's income, expenditure, and utility function are assumed to be the same before and after a price change, the concept of a *TPI* is closely related to that of a conceptual income compensation that must be added to (or subtracted from) his income to leave him as well off after the change in prices as he was before.[3] Thus, if we imagine a consumer beginning in a situation with period 0 prices and an income of M_0, he would be as well off after a price change to prices of period 1 when C_0, given by (1), is added to (or subtracted from) M_0.

$$C_0 = M_0(TPI_0 - 1) \tag{1}$$

The value TPI_0 is the *TPI* measured with the attained period 0 utility as a reference level. Similarly, if the consumer is imagined to begin in a situation 1 with an income of M_1, and then prices change to those of situation 0, the consumer would be as well off before as after the price change, if his income, M_1, is compensated by C_1, given by (2).

$$C_1 = M_1\left(\frac{1}{TPI_1} - 1\right) \tag{2}$$

The value TPI_1 is the *TPI* measured with the attained utility level of period 1 as the reference level of utility.

The fact that a consumer saves part of his income has not been explicitly considered in the literature dealing with the economic theory of index numbers, and it is the purpose of this paper to extend the theory to take account of this fact. Superficially the existence of saving might seem to pose no problem. If saving is considered as a good, then it has a price, and it might be thought that the existing theory is adequate to deal with it. For example, assume that a consumer with a money income of

* Assistant professor of economics, City College of the City University of New York. An earlier version of this paper was read at the December 1969 meetings of the Econometric Society.

[1] Situation 1 may be thought of as the current period and situation 0 a past period.

[2] See for example Melville Ulmer, especially ch. 3.

[3] Here it is assumed that if the consumer is on the same indifference surface before and after the price change, he really would obtain the same satisfaction in both situations. If this assumption is not made, an alternative approach is to reinterpret the *TPI* in the manner suggested by Franklin Fisher and Karl Shell and, likewise, to reinterpret the meaning of the income compensation. (This reinterpretation does not alter the formal definitions of a *TPI* or the income compensation.)

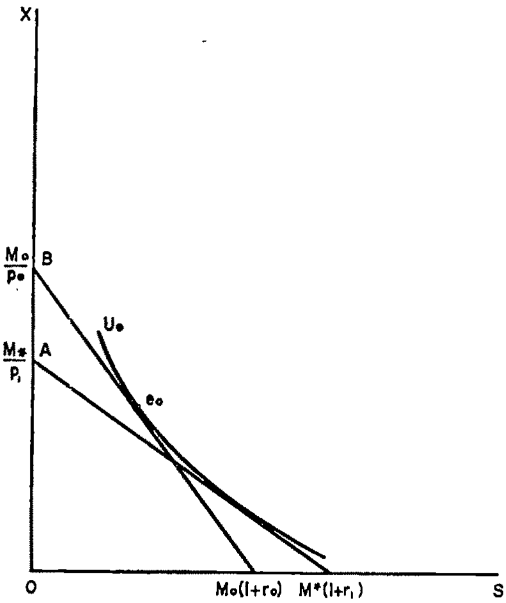

FIGURE 1

M_0 in period 0 has to decide how to allocate his income between one good X in amount x_0 and saving $S_0/(1+r_0)$, where r_0 is the market rate of interest. He has a utility function given by

$$U_0 = U(x_0, S_0) \tag{3}$$

and his budget constraint is

$$M_0 = p_0x_0 + S_0/(1 + r_0) \tag{4}$$

where p_0 is the unit price of X and $(1+r_0)^{-1}$ is the "price" per unit of saving owned at the end of period 0. The consumer would be in equilibrium at e_0 in Figure 1, attaining a utility level of U_0. Now, if in period 1 prices change to p_1 and $(1+r_1)^{-1}$, the minimum money income necessary to reach U_0 is M^*, and a *TPI* is defined as M^*/M_0 which is equivalent to $(OA\cdot p_1)/(OB\cdot p_0)$.

However, this analysis is inadequate because the consumer's saving decision is assumed to be made in a one period context and hence the reference level of utility is taken to be that of a single period for purposes of defining a *TPI*. Following the work of Irving Fisher, the modern view of the consumer's saving behavior is that he makes an intertemporal allocation of his expenditures to maximize an intertemporal utility function rather than a single period utility function.[4] It is this view of the consumer's saving decision which is accepted in this paper, and its implications for the measurement of the effect of price changes on a consumer who saves leads to the *TPI* which is discussed below.

In Section I, a basic model of the consumer's intertemporal decision making is constructed. In Section II, a *TPI* is defined, and then in Section III, the relationship of this *TPI* to the measurable Paasche and Laspeyres' price indexes is derived.

I. The Basic Model

We shall consider a consumer who has to allocate his expenditures between two periods, 0 and 1. He has an intertemporal utility function given by

$$W = W(U_0, U_1) \tag{5}$$

where

$$U_j = U(x_j) \quad \text{where} \quad j = 0, 1 \tag{6), (7}$$

is the utility level in period j. The utility function for each period is assumed to be the same and so are the n goods available for consumption. The term x_j is an n dimensional column vector of goods consumed in period j.

The consumer is assumed to know period 0 prices, p^0, with certainty at the beginning of period 0, and he expects the prices of these goods to be p_e^1 in period 1. He has these expectations at the beginning of period 0 and he acts as if he is certain that these prices will occur.[5] The terms p^0

[4] As another example of this approach, see the article by Menahem Yaari.

[5] Uncertainty may be introduced by assuming that at the beginning of period 0, the consumer has a subjective probability distribution for period 1 prices, and allocates his expenditures between the two periods to maximize the expected value of W. In this case, his

and p_e^1 are n dimensional row vectors. Further, it is assumed that he knows his money income M_0 and M_1 in the two periods and also r_0, the market rate of interest in period 0. We also assume that he is not concerned with periods after 1 and makes no allowance for a terminal stock of savings at the end of period 1.

The consumer is assumed to make his decisions at the beginning of period 0. Given p^0, p_e^1, M_0, M_1, r_0, and knowledge of (5), (6), and (7), he must then decide how to allocate his expenditure over periods 0 and 1. This results in a decision on how much he will save, S_0, in period 0.

Formally we may write out his process of decision making as follows: Find numbers S_0, U_0, U_1, and vectors x_j, $j=0, 1$ which maximize equation (5) subject to equations (6)–(9), and inequalities (10) and (11).

$$M_0 - S_0 = p^0 x_0 \tag{8}$$

$$M_1 + S_0(1 + r_0) = p_e^1 x_1 \tag{9}$$

$$-M_1/(1 + r_0) \leq S_0 \leq M_0 \tag{10}$$

$$x_j \geq 0, \qquad j = 0, 1 \tag{11}$$

The solution to this constrained maximization problem will yield the following: his planned saving $\overline{S}_0$;[6] the market baskets he plans to consume in periods 0 and 1, given by (12) and (13), respectively; his

$$\bar{x}_0 = (\bar{x}_{10}, \bar{x}_{20}, \ldots, \bar{x}_{n0})' \tag{12}$$

$$\bar{x}_1 = (\bar{x}_{11}, \bar{x}_{21}, \ldots, \bar{x}_{n1})' \tag{13}$$

planned single period utilities $\overline{U}_0$ and $\overline{U}_1$; and his planned intertemporal utility $\overline{W}$. The bar above a variable will be used to indicate a planned quantity of this variable decided on at the beginning of period 0. Also, it should be noted that constraint (10) allows for borrowing in period 0. Finally we define

$$\overline{E}_0 = M_0 - \overline{S}_0 \tag{14}$$

to be his planned expenditure in period 0, and

$$\overline{E}_1 = M_1 + \overline{S}_0(1 + r_0) \tag{15}$$

to be his planned expenditure in period 1.

II. The Definition of a True Price Index

There is a large degree of arbitrariness in the measurement of a conventional *TPI*, because many single period reference utility levels may be chosen. In the following definition of a *TPI* when the consumer saves a degree of arbitrariness remains. This stems not so much from the choice of a reference level of utility but rather from a choice of the period or periods in which the consumer's expenditure is assumed to be compensated for the price change. Since our basic model of saving is a closed two-period model, the effect of a price change is to move the consumer from the level of intertemporal utility that he would have attained had prices remained constant to the level of intertemporal utility he attains given actual period 1 prices. It is the intertemporal utility level that would be attained if prices remain constant which is taken as our reference utility level for measuring a *TPI*. This is an intertemporal level as opposed to the single period reference level of conventional index number theory. We shall not be concerned directly with the consumer's price forecasting ability, because his intertemporal expenditure allocation which partly depends on his price expectations, is made prior to his knowledge of period 1 prices, and is not affected by an actual change in prices. Now let us return to the situation of the consumer of the basic model at the beginning of period 1.

expenditures in the two periods will generally differ from his chosen expenditures in the basic model above. However, the argument in the remainder of the paper is not substantially changed when the basic model is replaced by this decision model with uncertain prices.

[6] $\overline{S}_0$ may be zero, but this does not affect the results of the paper.

In the beginning of period 1, the actual prices of period 1, $\hat{p}^1$, become known to the consumer. Let us assume that $\hat{p}^1$, p^0, and p_e^1 are three different price vectors.[7] This means that actual prices have changed and also that the consumer incorrectly forecast period 1 prices. His plans for period 0 have been realized, and his expenditure in period 1 is at the planned level of $\overline{E}_1$. However, given the actual prices of period 1, the consumer will purchase a market basket of $\hat{x}_1$ in period 1, and in general $\hat{x}_1 \neq \bar{x}_1$. Thus his actual utility level in period 1 will be $\hat{U}_1$ where

$$(16) \qquad \hat{U}_1 = U(\hat{x}_1)$$

and his actual level of intertemporal utility will be $\hat{W}$ where

$$(17) \qquad \hat{W} = W(\overline{U}_0, \hat{U}_1)$$

In general,[8] $\hat{U}_1 \neq \overline{U}_1$ and $\hat{W} \neq \overline{W}$. Hence the effect of an unanticipated price change is to change the consumer's single period utility in period 1 from that expected and has a corresponding effect on his intertemporal utility.

However, it is not the divergence of plans from realizations that we want to concentrate on, but rather the divergence of realizations from the situation that would have existed had prices remained constant. Assume now that $\hat{p}^1 = p^0$ and still that $p_e^1 \neq \hat{p}^1 = p^0$. In this case the consumer in period 1 with an expenditure of $\overline{E}_1$ would purchase a market basket $\tilde{x}_1$. In general $\tilde{x}_1 \neq \bar{x}_1$ and $\tilde{x}_1 \neq \hat{x}_1$. He would then attain a utility level in period 1 of $\tilde{U}_1$ where

$$(18) \qquad \tilde{U}_1 = U(\tilde{x}_1)$$

and an intertemporal utility level of $\tilde{W}$ where

$$(19) \qquad \tilde{W} = W(\overline{U}_0, \tilde{U}_1)$$

In general,[9] $\tilde{U}_1 \neq \overline{U}_1$, $\tilde{U}_1 \neq \hat{U}_1$, $\tilde{W} \neq \overline{W}$ and $\tilde{W} \neq \hat{W}$.

These relationships are shown in Figure 2 where the intertemporal utility function (5) is drawn in expenditure space with prices holding in periods 0 and 1 taken as parameters. Details of the construction of these intertemporal indifference curves are given in Appendix A. An intertemporal indifference curve is labeled by $W[p]$ where the actual level of intertemporal utility is shown by a symbol over the W and the prices holding in period 1 are shown by p. The price vector p may take three forms: p^0, implying that prices remain unaltered between periods 0 and 1; $\hat{p}^1$, the actual prices of period 1; and p_e^1, the prices expected in period 0 to hold in period 1. The intertemporal indifference curves in Figure 2 are drawn on the assumption that p^0, $\hat{p}^1$, and p_e^1 are three different price vectors.

The intertemporal budget constraint of the consumer is AB given by equation (20).

$$(20) \qquad E_0 = M_0 + (M_1 - E_1)/(1 + r_0)$$

In the beginning of period 0, he plans to be at C on AB spending $\overline{E}_0$ and $\overline{E}_1$ in periods 0 and 1, respectively, and attaining an intertemporal utility of $\overline{W}$ on $\overline{W}[p_e^1]$. Given his savings decision he is constrained to be at C, but because $p_e^1 \neq \hat{p}^1$, the level of intertemporal utility he actually attains is $\hat{W}$ on $\hat{W}[\hat{p}^1]$. If prices had remained constant between periods 0 and 1, his expenditure allocation at C resulting from his savings decision would have allowed him to achieve an intertemporal utility level of $\tilde{W}$ on $\tilde{W}[p^0]$.

This intertemporal utility level $\tilde{W}$ is taken as the reference level of utility for the purpose of defining a *TPI* when the consumer saves. If there had been no price change, he would have attained $\tilde{W}$. The effect of the price change is to give the con-

[7] See Appendix B where the implications of different relationships between $\hat{p}^1$, p^0, and p_e^1 are discussed.

[8] See Appendix B for the implications of exceptions to these "general" results.

[9] See Appendix B for exceptions to these relationships between the single and intertemporal utility levels.

sumer an intertemporal level of $\hat{W}$.

We now draw the intertemporal indifference curve $\tilde{W}[\hat{p}^1]$ in Figure 2. $\tilde{W}[\hat{p}^1]$ represents the level of intertemporal utility $\tilde{W}$, the same as the level of $\tilde{W}[p^0]$, but now the actual prices of period 1, $\hat{p}^1$, are the relevant parameters. Hence, if the consumer is to have his income adjusted to compensate for the price change in period 1, he must receive sufficient income to move from C to some point on $\tilde{W}[\hat{p}^1]$. This income compensation would enable the consumer to attain the same level of intertemporal utility he would have attained had prices remained unchanged.

Here is where the main degree of arbitrariness arises in defining a *TPI* when the consumer saves, for clearly this income adjustment could be made in numerous ways. For example, we could use as the compensated level of income the present value of that smallest income stream which would just be sufficient to move the consumer from C to $\tilde{W}[\hat{p}^1]$.[10] This income stream divided by his actual present value of expenditures would provide a *TPI*. Alternatively we might imagine a conceptual expenditure adjustment in period 0

[10] Where E_1 is discounted by $(1+r_0)$.

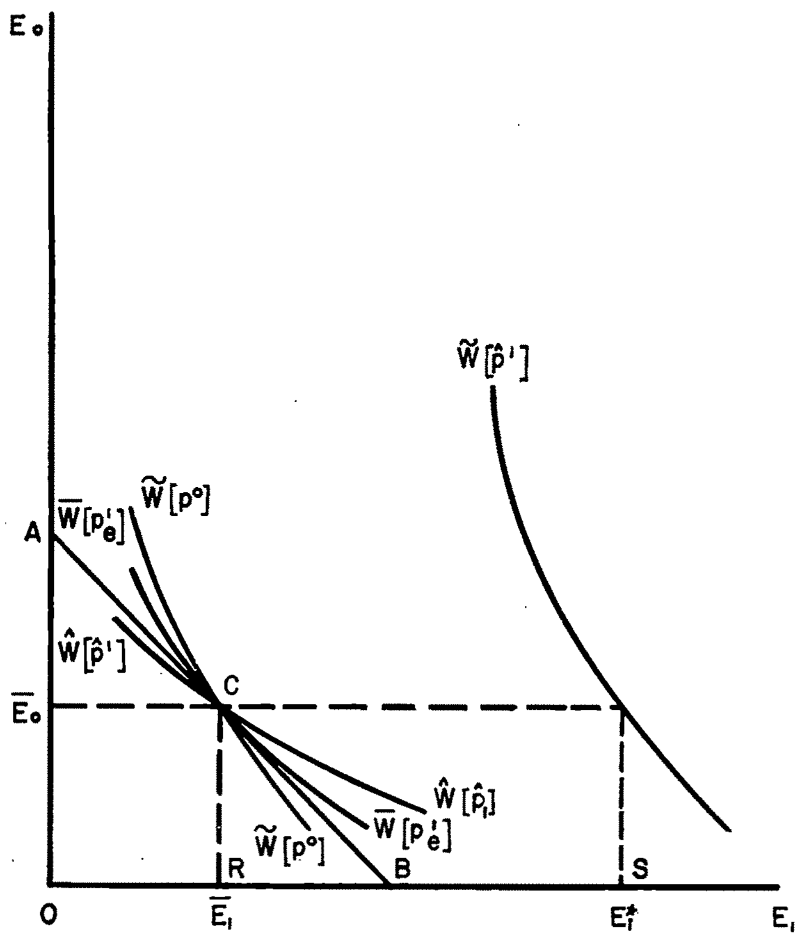

Figure 2

which is just sufficient to raise the consumer from C to some point on $\tilde{W}[\hat{p}^1]$.[11] This expenditure level divided by $\bar{E}_0$ would give a different TPI.

In this paper we shall assume that the compensation to his expenditure is made only in period 1. This is done for operational purposes, for once a price change has taken place the consumer cannot be compensated in period 0, but he can be compensated in period 1. Hence the minimum expenditure compensation in period 1 necessary to move the consumer from C to $\tilde{W}[\hat{p}^1]$ is $E_1^*-\bar{E}_1$, and we define a TPI as

$$TI = E_1^*/\bar{E}_1 \tag{21}$$

where E_1^* is the minimum expenditure the consumer needs in period 1 to achieve the level of intertemporal utility he would have achieved had prices remained constant, and $\bar{E}_1$ is his actual expenditure in period 1. Thus the situation of Figure 2 represents a true price increase for the consumer and the TI is given by OS/OR.

The effect of choosing period 1 for compensating the consumer's expenditure means that the measurement of a TPI when the consumer saves, based on an intertemporal reference utility level of $\tilde{W}$, is reduced to the measurement of a conventional TPI based on the single period reference utility level $\tilde{U}_1$. However, this TPI, TI defined in (21), is not the one that is usually measured. Rather $\bar{U}_0$ or $\hat{U}_1$ are taken as single period reference utility levels for measuring a TPI.

It has been assumed above that the price vectors p_e^1, p^0, and $\hat{p}^1$ are actually different from each other, and that the levels of intertemporal utility $\bar{W}$, $\tilde{W}$, and $\hat{W}$ are also different. In Appendix B the implications of alternative relationships between these prices and intertemporal utility levels are considered. It should be noted that a necessary condition for the TI to equal unity is that $\tilde{W}[\hat{p}^1]$ passes through C in Figure 2. This will happen when $p^0=\hat{p}^1$, a sufficient but not a necessary condition for the TI to equal unity. Further, the consumer's price forecasting ability is shown by how close $\bar{W}[p_e^1]$ is to $\hat{W}[\hat{p}^1]$ in Figure 2. If he correctly forecasts period 1 prices, these two intertemporal indifference curves are identical, represent the same level of intertemporal utility, and are tangent to AB at C. But no matter how proficient the consumer is in forecasting prices, the TI will only be unity when $\tilde{W}[\hat{p}^1]$ passes through C.

[11] This compensation would be added as a lump sum to $\bar{E}_0$.

III. The Relationship Between the True Price Index and Measurable Indexes

If we knew the form of the single period utility functions (6) and (7) and the intertemporal function (5), then the TI given by (21) could be measured exactly. Without knowledge of these functions, however, the TI may be related to measurable Paasche and Laspeyres' price indexes. As we would expect these results differ from the conventional ones because in effect our TI is a conventional TPI based on a single period utility level which is not generally used as the reference level of utility.

First we shall consider the relationship of the TI to the Paasche price index (PI). The compensated income in period 1 is E_1^* where

$$E_1^* = \hat{p}^1 x_1^* \tag{22}$$

The market basket, x_1^*, that the consumer would purchase in period 1 with his compensated expenditure is indifferent to $\bar{x}_1$ for him, since they would both yield him $\tilde{U}_1$ in period 1. Thus we may write

$$\bar{x}_1 I x_1^* \tag{23}$$

where I indicates indifference between market baskets. The PI is given by

$$PI = \bar{E}_1/E_1^+ \tag{24}$$

where

$$E_1^+ = \overset{0}{p}\hat{x}_1 \tag{25}$$

and

$$\overline{E}_1 = \overset{1}{\hat{p}}\bar{x}_1 = \overset{1}{p_e}\bar{x}_1 = \overset{0}{p}\bar{x}_1 \tag{26}$$

It should be remembered that with an expenditure of E_1^* and period 1 prices, the consumer would be observed to purchase x_1^*; with an expenditure of $\overline{E}_1$ and period 0 prices, the consumer would be observed to purchase $\bar{x}_1$; and with an expenditure of $\overline{E}_1$ and actual period 1 prices, the consumer is observed to purchase $\hat{x}_1$. However, E_1^+ is simply the cost of $\hat{x}_1$ at period 0 prices, and the consumer will not in general be observed to purchase $\hat{x}_1$ with an expenditure of E_1^+ and period 0 prices.

With this information the following results may be derived relating the TI to the measurable PI:[12]

THEOREM 1: When the $PI>1$, the $TI>1$

THEOREM 2: When the $TI<1$, the $PI<1$

THEOREM 3: When the $TI=1$, the $PI \leq 1$

THEOREM 4: When the $PI=1$, the $TI \geq 1$

The statements $PI=1$ and $TI=1$ in Theorems 3 and 4, respectively, hold only when $\hat{p}^1=p^0$. As an example we shall prove Theorem 1.

PROOF of Theorem 1:

When the $PI>1$, we have

$$\overline{E}_1 > E_1^+ \tag{27}$$

hence from (25) and (26)

$$p^0\bar{x}_1 > p^0\hat{x}_1 \tag{28}$$

which implies that

$$\bar{x}_1 RPT \hat{x}_1 \tag{29}$$

where RPT stands for "revealed preferred to" and we use the axioms of the theory of revealed preference.[13] Then from (23) and (29), we have

$$x_1^* RPT \hat{x}_1 \tag{30}$$

hence

$$\overset{1}{\hat{p}}\hat{x}_1 < \overset{1}{\hat{p}}\overset{*}{x_1} \tag{31}$$

hence

$$\overline{E}_1 < E_1^* \tag{32}$$

Combining (27) and (32), we have

$$E_1^* > \overline{E}_1 > E_1^+ \tag{33}$$

that is

$$E_1^*/\overline{E}_1 > 1 > (\overline{E}_1/E_1^+)^{-1} \tag{34}$$

hence

$$TI > 1 > 1/PI \tag{35}$$

therefore

$$TI > 1 \tag{36}$$

and Theorem 1 is proved. Notice that nothing is indicated about the relative size of the PI and the TI.

The proofs of Theorems 2 to 4 and the remaining one of this section will be provided by the author on request. They are similar to that of Theorem 1. In relating the TI to the PI, we are able to rank the PI and the TI only in the case when the $PI=1$. In this situation, the PI will be a lower bound on the TI if $\hat{p}^1 \neq p^0$, and equal to the TI if $\hat{p}^1=p^0$.

We can get additional information in

[12] The consumer is assumed to strongly order his preferences, i.e., he will always purchase a unique market basket when he has a given money expenditure and faces the same market prices. (See the work by John R. Hicks, especially ch. 5.) This assumption is not necessary for the proofs of all the theorems.

[13] We shall use the symbol RPT if it is valid, either for a conceptual experiment concerning the behavior of the consumer in a given price and income situation, or for actual observations on a consumer who behaves according to the basic model.

some circumstances by relating the TI to the measurable Laspeyres' price index (LI), where

$$LI = \hat{p}^1\bar{x}_0/p^0\bar{x}_0 \tag{37}$$

The following theorem may be proved:[14]

THEOREM 5: When $\overline{E}_0 \geq \overline{E}_1$, then

$$TI \leq (\overline{E}_0/\overline{E}_1)\cdot LI \tag{38}$$

The equality in (38) holds only when $\overline{E}_0 = \overline{E}_1$ and $\hat{p}^1 = p^0$. In this case Theorem 5 reduces to the result that the $TI = 1$. When $\hat{p}^1 = p^0$, but $\overline{E}_0 > \overline{E}_1$ we have a trivial upper bound on the TI; trivial because with stable prices, the $TI = 1$.

Because $\overline{E}_0 \geq \overline{E}_1$, the LI does not provide an upper bound to the TI except in the case when $\overline{E}_0 = \overline{E}_1$. When $\overline{E}_0 < \overline{E}_1$ a relationship between the TI and the LI cannot be derived.

The results of Theorems 1, 4, and 5 are combined in Table 1. The equalities of the TI to 1 and the LI in the third row of the table hold if and only if $\hat{p}^1 = p^0$, in which case $PI = LI = TI = 1$. The only situation when the PI and LI provide no information concerning the TI is when the $PI < 1$ and $\overline{E}_0 < \overline{E}_1$.

TABLE 1

PI	$\overline{E}_0<\overline{E}_1$	$\overline{E}_0=\overline{E}_1$	$\overline{E}_0>\overline{E}_1$

IV. Concluding Remarks

In this paper a TPI has been defined for a consumer who saves in order to maximize a simple two-period intertemporal utility function. There are several extensions of this analysis which will be dealt with in a subsequent paper. For example, we will examine how the consumer's desire for a terminal stock of savings in period 1 affects the analysis. Also the model will be extended beyond two periods and a TPI will be defined to measure price changes between different periods. In this analysis the consumer's revisions of his price expectations will play an important role.

[14] Theorem 5 is proved by showing that when $\overline{E}_0 > \overline{E}_1$, then $E_1^* < \hat{p}^1\bar{x}_0$, and when $\overline{E}_0 = \overline{E}_1$, then $E_1^* \leq \hat{p}^1\bar{x}_0$, the equality holding only when $\hat{p}^1 = p^0$.

APPENDIX

A. *Construction of Intertemporal Indifference Curves in Expenditure Space*

Assume that the level of intertemporal utility in equation (5) is held constant at some level, say W^+. The intertemporal indifference curve representing W^+ in utility space is then given by the set of utility pairs A^+ where $A^+ = [(U_0, U_1) \mid W^+ = W(U_0, U_1)]$. Now suppose that we choose any price vectors p_+^0, p_+^1, holding in periods 0 and 1, respectively. Then for each element of A^+ we may find the minimum expenditures pair (E_0, E_1) needed to attain it given the prices p_+^0 and p_+^1 holding in the two periods. When we do this for each element of the set A^+ and the chosen prices p_+^0, p_+^1, we have a set of expenditure pairs which is an intertemporal indifference curve in expenditure space representing an intertemporal utility level of W^+. We symbolize such an indifference curve by $W[p_+^0, p_+^1]$. If the level of intertemporal utility is held constant and different price vectors are chosen, the intertemporal indifference curve in expenditure space representing a level of utility of W^+ will be different in general from $W[p_+^0, p_+^1]$.

In the situations considered in this paper, the price vector of period 0 is always that of p^0, the actual prices in period 0. Hence, the intertemporal indifference curves will be symbolized by $W[p_+^1]$ where the symbol over the W indicates the level of intertemporal utility of an indifference curve and the price vector is a price vector assumed to hold in period 1. Finally, we shall assume that no two intertemporal indifference curves are identical in expenditure space unless the price situations of period 1 are the same. Thus two identical curves must represent

TABLE 2—POSSIBLE RELATIONS BETWEEN p, U, AND W, AND VALUE OF TRUE PRICE INDEX

p	U	W	TI
1. $p_e^1=p^0=\hat{p}^1$	(a) $\tilde{U}_1=\overline{U}_1=\hat{U}_1$	$\tilde{W}=\overline{W}=\hat{W}$	$TI=1$

	(b) $\tilde{U}_1=\hat{U}_1=\overline{U}_1$	$\tilde{W}=\hat{W}=\overline{W}$	$TI=1$
5. $p_e^1\neq\hat{p}^1\neq p^0$	(a) $\tilde{U}_1\neq\overline{U}_1\neq\hat{U}_1$	$\tilde{W}\neq\overline{W}\neq\hat{W}$	$TI\neq 1$
	(b) $\tilde{U}_1\neq\overline{U}_1=\hat{U}_1$	$\tilde{W}\neq\overline{W}=\hat{W}$	$TI\neq 1$
	(c) $\tilde{U}_1=\overline{U}_1\neq\hat{U}_1$	$\tilde{W}=\overline{W}\neq\hat{W}$	$TI\neq 1$
	(d) $\tilde{U}_1=\hat{U}_1\neq\overline{U}_1$	$\tilde{W}=\hat{W}\neq\overline{W}$	$TI=1$
	(e) $\tilde{U}_1=\hat{U}_1=\overline{U}_1$	$\tilde{W}=\hat{W}=\overline{W}$	$TI=1$

the same level of intertemporal utility. The odd cases we are not considering are those where two different price situations in period 1 may yield identical curves (or curve segments) in expenditure space which may or may not represent the same intertemporal utility level.

B. *Alternative Relationships Between Price Vectors and Utility Levels*

For the consumer who has attained a utility of $\overline{U}_0$ in period 0 and has $\overline{E}_1$ to spend in period 1, we may imagine three possible price situations in period 1, indicated by p_e^1, $\hat{p}^1$, and p^0, the vectors of expected period 1 prices, actual period 1 prices, and period 0 prices, respectively. In each of these price situations, we may evaluate his period 1 utility levels $\overline{U}_1$, $\hat{U}_1$, or $\tilde{U}_1$, given $\overline{E}_1$, and thus his resulting intertemporal utility $\overline{W}$, $\hat{W}$, or $\tilde{W}$, given $\overline{U}_0$. However, there are five possible relationships of equality and/or inequality

between p_e^1, $\hat{p}^1$, and p^0, for example, $p_e^1 \neq \hat{p}^1 = p^0$. For each of these relationships there will be at least one possible relationship of equality and/or inequality between $\bar{U}_1$, $\hat{U}_1$, and $\tilde{U}_1$, and equivalently between $\overline{W}$, $\hat{W}$, and $\tilde{W}$. For each of these possible sets of relationships we may determine whether or not the true price index differs from unity. All the possible situations are given in Table 2.

The *TI* is only unity when $\tilde{U}_1 = \hat{U}_1$, i.e., when $\tilde{W} = \hat{W}$, regardless of the relationship of $\bar{U}_1$ to $\tilde{U}_1$ and $\hat{U}_1$, and thus regardless of the relationship of $\overline{W}$ to $\tilde{W}$ and $\hat{W}$. Diagrammatically we may illustrate these relationships in the two-good case by using conventional indifference curve analysis, and in the *n*-good case by using intertemporal indifference curves drawn in expenditure space. As an example let us compare situation 5(a) with 5(d). In Figure 3 situation 5(a) is drawn for the case of two goods X_1 and X_2, and in Figure 4 situation 5 (a) is drawn using intertemporal indifference curves for a situation when the *TI* indicates a fall in prices. In Figures 5 and 6 situation 5(d) is drawn and in this situation the *TI* must be unity.

In all possible situations, however, the *TI* depends on a comparison between $\hat{U}_1$ and $\tilde{U}_1$, and will only be unity when $\hat{U}_1 = \tilde{U}_1$, i.e., when $\hat{W} = \tilde{W}$. From the analysis in this Appendix we see that this will certainly be the case when $p^0 = \hat{p}^1$, but this is a sufficient and not necessary condition for true price stability.

Theories of Corporate Investment Behavior Revisited

By J. W. ELLIOTT*

Dale Jorgenson's investment model has been extensively tested and analyzed at aggregate and at industry levels, particularly within the manufacturing sector.[1] It has also been evaluated in this *Review* at the level of the firm.[2] In this latter evaluation, rather general conclusions were drawn from a sample of fifteen large manufacturing firms as to the performance rankings of alternative investment models. These rankings were based principally on the size of residual variation resulting from successively inserting each model into the flexible accelerator mechanism fit to time-series data of the individual firms. Jorgensen and Siebert interpreted the results as showing the superiority of the neoclassical theory of investment over other considered alternatives.

Even aside from lingering criticisms of Jorgenson's model such as that of Robert Eisner (1970), and Eisner and M. Ishaq Nadiri, the Jorgenson and Siebert (JS) firm-level results are based on a rather meager sample (fifteen firms) given the apparently general objectives of their work.

Greater meaning may be attached to the JS conclusions either by expanding their time-series sample to cover more firms or to conduct their comparison of alternative investment models on a cross-sectional basis. The cross-sectional alternative is attractive in that a great many cells of firm-level data may be evaluated in a manner leading to results with some general significance. Patterns which emerge from cross-sectional tests on individual firm data will reflect relationships persisting across firm and industry boundaries.

Further, as Edwin Kuh has pointed out, the impact of "inter-firm dynamic specification difficulties will be less in cross-sections since market or cyclical factors faced in common by all firms in an industry will not affect inter-firm variability and therefore will exert a minor influence on cross-section estimates" (p. 185). However, as Kuh also recognizes, cross-sections are likely to be relatively poor vehicles for analysis when dynamic disturbances are present and unaccounted for by the model (p. 328). This implies that the reasonableness of cross-section results depends somewhat on the correctness of the dynamic model specification. In the present case, this amounts to accepting the flexible accelerator and Jorgenson's generalized Pascal distributed lag structure a priori.

In addition, the use of time-series data to empirically fit the lag structure in the JS study led to measured coefficients representing a single characterization of the lag pattern over the sample period for each firm. Following the same procedure in cross-sections leads to selection of a single measured lag structure for each year best representative of the sample firms. To the extent that parameters of the true lag pattern vary intertemporally there may be advantages in the cross-section approach which outweigh disadvantages associated with selecting a single lag structure for the entire sample.

In the JS study it was simply concluded a priori that "In order to specify the lag structure correctly we concentrate on time series data for individual firms" (1968a, p. 690). When the objective is to extract generalizable patterns from firm-level data, the choice of time-series does not seem as straightforward as this statement would have us believe. Indeed, it is difficult to define a clear-cut case a priori for the direction of analysis of firm-level data in such a case.

* University of Wisconsin, Milwaukee. I wish to thank Dale Jorgenson and Calvin Siebert for supplying representative data on their variables, Naime Sherbiny and several unnamed referees for their constructive help in this project, and the Graduate School of the University of Wisconsin-Milwaukee for computer facilities and assistance.

[1] See for example, Jorgenson (1963) and Jorgenson and Robert Hall, plus several of Jorgenson's more recent works.

[2] See Jorgenson and Siebert (1968a). The identical sample is used in Jorgenson and Siebert (1968b).

In expanding the basis for the JS comparison, this led to analysis of a much enlarged firm-level sample on both a time-series and cross-sectional basis, which taken together should help clarify the meaning of resulting conclusions.

Accordingly, data on the JS variables were developed from 184 firms inside and outside manufacturing. These firms are drawn from 72 four-digit SIC-level industries. The specific industries and numbers of firms are shown in Table 1. Data on firm variables were obtained for 1953–67 from Standard and Poor's Compustat data bank. Selection of firms was made on the basis of: a) available data; b) no greater than five firms per industry; c) compatibility in accounting practice over the sample period. These criteria were aimed at developing a broadly based sample of large firms.

Analysis of the data was undertaken for each of the years 1953–67, and for each of the 184 firms separately. One definitional change was made from the JS definitions, relating to

deflators. Because the cross-sectional test invites heteroscedasticity due to inter-firm differences, all variables employed in the JS analysis which were not unit free were deflated by the firm's total assets, thus greatly reducing inter-firm differences in magnitude. This made our investment measure a representation of capital investment intensity rather than direct volume of spending.[3]

This is not a trivial difference and raises the possibility that our enlarged results may only be applicable to intensity of investment (per dollar of total assets) and not to raw volume of investment. Fortunately, the smoothness of typical total asset series compared to investment series appears to reduce this possibility greatly. In addition, it is difficult to believe that fundamental inter-model differences in explanatory power will not emerge given investment intensity rather than volume as the dependent variable.

To compare major alternative investment models, JS employed the well-known flexible accelerator framework in which:

$$(1)\quad K_t - K_{t-1} = (1-\lambda)(K_t^* - K_{t-1})$$

where K_t and K_t^* are actual and desired levels of capital in period t. Assuming replacement to be a constant proportion, δ, of capital enables the change in capital to be expressed as:

$$(2)\quad K_t - K_{t-1} = E_t - \delta K_{t-1}$$

where E_t is the level of new capital expenditures. Expressions (1) and (2) may be combined to produce a flexible accelerator framework for analysis of investment expenditures:

$$(3)\quad E_t = (1-\lambda)(K_t^* - K_{t-1}) + \delta K_{t-1}$$

To complete the model it is necessary to specify the determinants of the desired level of capital stock. It is at this point that theoretical conflicts most clearly occur, as different investment theories have emphasized the primacy of varying principal influences on K_t^*. Based on this view, the JS comparison defined alternative representations of K^* reflecting major branches of investment theory. The statistical importance of each K^* measure was evaluated by its separate insertion in an operational version of the flexible accelerator framework of (3).

This operational version derives from generalizing the flexible accelerator and assuming the distributed lag influence of each K^* on E_t follows a generalized Pascal distribution. JS show that generalizing (3) gives

$$(4)\quad E_t = \sum_{r=0}^{\infty} \mu_r (K_{t-r}^* - K_{t-r-1}^*) + \delta K_{t-1}$$

where the μ_r are weights which are non-negative and sum to unity. Incorporating their lag specification gives:

$$(5)\quad \begin{aligned} E_t = &\sum_{r=0}^{2} \mu_r (K_{t-r}^* - K_{t-r-1}^*) \\ &- \sum_{i=1}^{2} w_i (E_{t-i} - \delta K_{t-i-1}) + \delta K_{t-1} \end{aligned}$$

which is the specific model used to compare the relevance of alternative desired capital stock specifications. In this model, up to three desired capital stock and up to two lagged net investment terms were admitted into the specification of the distributed lag, based on their explanatory impact on investment. Terms were added to the equation if they lowered the standard error.

Four theoretical alternatives are reflected in the competing specifications of the K^* terms in (5). These include:

(I_{cl}) The neoclassical formulation of Jorgenson which sees K^* as proportional to output (Q) and the user cost of capital services (C), i.e.,

$$K^* = \propto \left(\frac{pQ}{C}\right)$$

where p = product price and $\propto$ is a proportionality constant.

[3] The National Industrial Conference Board fixed capital stock deflators were used at several points in the analysis, following Jorgenson. However, in our case involving some nonmanufacturing firms in the sample, their use relies on the assumptions that price changes for capital goods purchased by nonmanufacturing firms were approximately the same as price increases on purchases by manufacturing firms.

(I_a) A capacity utilization or accelerator model is based on output changes devised to represent the work of Kuh, Eisner, and Hickman:

$$K^* = \propto Q$$

(I_l) A model measuring cash flow, (L), proposed to measure cash flow effects similar to those found important by Grunfeld and Kuh:

$$K^* = \propto L$$

(I_{exp}) An expected profits model built on the market value of the firm, (V) as suggested by Grunfeld:

$$K^* = \propto V$$

For details of the statistical formulation of these competing investment models, the reader should consult the statistical appendix of a working paper available from JS.

JS also considered a second version of the neoclassical model which treated capital gains effects explicitly. This second version is considerably more demanding computationally; therefore, it did not seem necessary to include both versions in the analysis. Moreover, the two versions ranked next to each other in all performance comparisons.

Following JS, current, one-, and two-lagged changes in each alternative K^* representation (I variable) were inserted into (5) and retained if they contributed to the explanation of investment intensity by lowering the standard error of estimate. One- and two-lagged values of the net investment term of (5) were included on the same basis. With this procedure, the most empirically significant I model should provide a superior explanation of fluctuations in investment intensity in a high number of sample firms. Accordingly, the four competing I models are ranked on the basis of the size of the standard error resulting from their employment as explanatory variables for investment intensity in (5).

Some representative results of the time-series tests are shown in Table 2. Coefficients, standard errors, and goodness-of-fit data are shown for eleven firms, drawn from the eleven major industrial groupings in the sample. These groupings are discussed below in connection with the homogeneity tests. The firms shown are the first in each major industrial grouping. Similar data on the cross-sectional tests are given in Table 3 for each of the 15 years in the sample. The time-series R^2 values are comparable with those obtained by JS, thus suggesting that the use of investment intensity in place of volume did not noticeably damage the level of explanation. However, for the expanded time-series firms, the measured direction of effect of the desired capital stock proxies is not consistent across firms. This contrasts with the JS results which were uniform in direction of effect for all desired capital stock proxies except the liquidity model.[4]

The sign inconsistencies observed in the present work may be simply due to the multicollinearity frequently found. In fact, in many instances, attempts to even compute the determinant of the correlation matrix of independent variables in order to calculate a chi-square statistic for Wilks-Bartlett's approximate test for multicollinearity were frustrated by the severity of the condition. In any event, the frequency with which multicollinearity was evident in the present results reduces greatly the inferences we may draw from observed values of individual coefficients. Fortunately, this condition does not damage the usefulness of the present results for comparing alternative desired capital stock proxies on the basis of their impact on explained variation in investment intensity.

In the cross-sections, the level of explanation remains reasonably high for most desired capital stock proxies in most years.[5] This as much as anything suggests broadly based intertemporal support for the flexible accelerator mechanism. The inconsistency in the direction of effect of all the desired capital stock proxies observed in the time-series data remains, as does the appearance of multicollinearity.

[4] Although coefficients were not included in the JS article, they were included in a longer working paper supplied by the authors.

[5] For the degrees of freedom involved ($n=184$), R^2 values of as low as .10 are significantly different from zero beyond the 1 percent level.

These cross-sectional results relative to the I_a variable present an opportunity for some comparisons with recent empirical work by Robert Eisner. In 1969, he explored the cross-sectional relevance of a number of explanatory mechanisms involving sales change, profits, and depreciation in explaining variation in a measure of investment intensity very similar to that used in the present work. Among his results is the finding that the distributed lag effect of his sales-change variable is unstable intertemporally in cross-sectional tests. Eisner suggests this may be due to marked differences in growth rates in sales before and after 1960. The I_a variable of the present comparison is roughly com-

parable with his sales change variable.[6] Our sign inconsistencies in the I_a variable in the present work are generally similar to his results, but do not show any particular breakpoint in pattern before and after 1960. However, at least in the present analysis, the observed inconsistencies may be entirely due to a suspiciously high level of multicollinearity.[7]

Troublesome as these sign inconsistencies might be, they do not directly relate to the principal data upon which the JS conclusions are based. These data emerge for each firm from a ranking of standard errors resulting from the best-fitting distributed-lag specification for each desired-capital-stock proxy. For our expanded sample, such residual-variation comparisons have been prepared for both the time-series and cross-sectional results, and shown in Table 4. In Table 4, the standard error for each of the four models has been ranked for each of the 184 firms in the enlarged time-series sample. The model listed vertically on the Y axis had a lower standard error than the model listed horizontally on the X axis in the number of cases shown.

One aspect of these expanded time-series rankings of particular interest is the extent to which they reflect systematic industry differences in model rankings. If important differences in residual variance rankings is

[6] Eisner deflated his sales change terms by a moving average of past or base period sales change, while our I_a sales change term was deflated by past total assets. This prohibits comparisons between coefficient magnitudes. However, the significance of t-values can be reasonably examined.

[7] However, Wilks-type F-values suggest that the presence of multicollinearity in the present cross-section is most severe among desired capital stock terms. This indicates the total summed effect of a desired capital stock coefficient will be more reliable than individual terms. However, substantial intertemporal instability continues to be present in the summed cross-sectional effect of the I_a term, which is suggestive of Eisner's result.

TABLE 4—MODEL RANKINGS[a]

JS Comparisons: 15 Firms (1949–63)

Enlarged Comparisons: 15 Years (1953–67); 184 Firms
Cross-Section

	I_l	I_a	I_{exp}	I_{cl}
I_l	—	9	9	13
I_a	6	—	9	9
I_{exp}	4	4	—	7
I_{cl}	2	3	5	—

[a] The overall JS ranking is: I_{cl}; I_{exp}; I_a; I_l. The neoclassical I model (containing capital gains effects) has been eliminated from this comparison. It ranked slightly above the simpler neoclassical II model, I_{cl} (superior in 8 of 15 firms in the standard error criterion) and was almost identical on other criteria used.

attributable to industry, then our overall rankings become a product of the choice of industrial sample, and the meaning of the results of Tables 4 and 5 is altered accordingly. To test for industry-homogeneity of the obtained rankings, a chi-square test was employed. Combinations of two-digit level industries were formed to produce groupings of at least ten firms, having either single or side-by-side two-digit codes. The overall ranking proportions for each model were used as the basis of the expected frequencies in each industrial grouping. A smallest-cell overall proportion of .216 required at least ten firm groupings in order to produce a minimum expected cell frequency greater than 2, a requirement for the test. The industrial groupings, numbers of firms, and calculated chi-square values are shown in Table 6. As seen, only one industrial segment, Food and Beverages was significantly nonhomogeneous at the 5 percent level, producing a value significant at approximately the 4 percent level. This suggests the obtained results are largely free of substantial industry effects, and are not particularly due to the industry composition of the enlarged sample.

However, since this may not be true of the Food and Beverage segment of our sample, it is of interest to examine these results separately. Table 7 shows model comparisons similar to those of Table 4 for the twenty-seven Food and Beverage firms in the sample. As seen, the impact of the nonhomogeneity is mainly upon the ranking of the neoclassical model, which moves from an overall ranking of third to first among these firms, while other models remain in the same relative position as in the overall rankings. This suggests that the appearance of twenty-seven Food and Beverage firms in the sample may somewhat unduly influence the results in favor of the neoclassical explanation of investment. In Table 8, the time-series comparisons of Table 4 are recomputed omitting the Food and Beverage firms. As seen, little impact on the overall rankings results. Taken together, the results of Tables 6, 7, and 8 suggest that our rankings and model comparisons are largely unaffected by the industry composition of the sample, although some

bias in favor of the neoclassical model may be present due to the Food and Beverage segment of the sample. With this possibility noted, we may consider the present results in light of those of JS.

Unlike the JS results, the enlarged comparisons reveal that only small differences can be identified in the overall relative importance of the liquidity, accelerator, and classical models, while a slight inferiority of the expected profits model to the other three is revealed. In the cross-sections, a clearer separation in the rankings appears, with the liquidity model being the most effective determinant of desired capital stock in nine of fifteen comparisons with the accelerator model, nine of thirteen comparisons with the expected profits model, and thirteen of fifteen comparisons with the neoclassical model. Similarly, the accelerator model is more effective than either the expected profits or neoclassical model while the neoclassical model is the least effective of those evaluated cross-sectionally.

I_{exp}	67	65	64	—

The relatively weak explanatory power of the expected profits proxy in our tests may shed some light on an earlier finding by Eisner (1967) that the rate of return on market value of the firm does not prove statistically significant in cross-sections and has a negative coefficient in firm-level time-series. Our $I_{\exp}$ variable is a measure of firm market value similar to the denominator in his expression. We find the total distributed lag effect of this variable to be inconsistent in direction in both time-series and cross-sections, and to be generally inferior in its explanatory significance. This suggests that Eisner's finding may be due to the lack of significance and consistency which attaches to the market-value measure in the denominator of his expression.

Furthermore, the relatively strong cross-sectional showing of the capacity-utilization-accelerator I_a variable relative to other desired capital stock proxies suggests a more Eisner-like and a less Jorgenson-like view of

corporate investment functions may be more appropriate than that indicated by the JS study. In fact, the accelerator proxy provided a better explanatory variable than the neoclassical model in nine of twelve cross-sectional comparisons. However, this view is not wholly reinforced by the time-series results which show the two to be virtually indistinguishable in the overall comparison and which show the accelerator explanation slightly superior to the neoclassical explanation (79 of 150 comparisions) in the homogeneity-corrected sample. Moreover, the rather high R^2 values for the cross-sectional tests of the I_a variable support Eisner's (1967) conclusion that the role of past sales changes in cross-sections is significant, presumably as a proxy for expected long-run pressures of demand on capacity.[8]

Based on strict numerical rankings, the results of the enlarged time-series and of the cross-sections agree in assigning the highest ranking to the liquidity model, I_l, and the second ranking to the accelerator model, I_a. For the third and fourth ranks, the neoclassical and expected profits models are reversed in the cross-sections from the time-series. With the earlier noted differences in the nature of cross-sectional and time-series evidence, the general correspondence in rankings suggests that the comparative effectiveness of the alternative models does not strongly depend upon the choice of time-series or cross-sectional perspective.

An additional comparison with JS can be obtained by following their procedure of enumerating the coefficients for the desired capital stock terms for each model. The frequency with which a desired capital stock term was included in an equation is taken by JS as an indication of its empirical importance. More significant desired capital stock proxies would lower the residual variation of the investment equation more frequently than less significant proxies, and would therefore be included and assigned nonzero values more frequently. Table 5 shows these results, along with those of JS. In the enlarged time-series and in the cross-sections, only small numerical differences separate the included coefficients for the four models, leaving an inconclusive picture on this criterion.

Taken together with the rankings of Table 4, the overall impression is that important differences in the empirical relevance of alternative models do not appear in our enlarged time-series sample. Some ability to distinguish among models derives from the cross-sections, and suggests that the liquidity explanation is the most effective alternative considered.

Thus, the major conclusion of the JS study that the neoclassical model of investment is more effective than other alternatives simply does not stand up to the enlarged test, and must now be interpreted as having no general implications beyond their sample. Other conclusions, such as their rejection of the liquidity model as a serious explanatory mechanism, must be similarly reinterpreted to apply to a much smaller set of firms. In the enlarged sample, the liquidity explanation of investment is among the most effective available.

The present finding is also of interest in light of the information content of the alternatives defined by JS. The accelerator, expected profits, and liquidity models are each functions of a single variable while the neoclassical model incorporates several variables including those comprising the accelerator and expected profits models. That the greater assemblage of information does not improve (and detracts from) the results obtained by the simpler models does not speak well for the empirical pertinence of the neoclassical formulation. Furthermore, the market value of the firm contained in both the expected profits and neoclassical formulations appears if anything to be an inferior means by which to explain investment behavior when employed either as an expectations or cost-of-capital measure.

Finally, evidence is accumulating which suggests that several of the variables involved in the JS comparison may be jointly determined along with investment as parts of a simultaneous system of corporate financial behavior. Empirical results by Mueller,

[8] Again, the differences in definition of sales change should be considered. See fn. 6.

Dhrymes and Kurz, and Elliott in particular lead in this direction. Under such circumstances, the single-equation structure of such a comparison may be inappropriate. Even putting this possible difficulty aside, the clearest indication obtained by the present results is that the most relevant explanatory model for individual corporate investment behavior is not the neoclassical framework of JS but an open question in need of more inquiry.

Unemployment and Consumption: Note

By MICHAEL GROSSMAN*

According to a new approach to demand theory, households produce the commodities that enter their utility functions with inputs of market goods and their own time (see Gary Becker, Becker and Robert T. Michael, Kelvin Lancaster, Richard Muth). Provided time and goods were not employed in fixed proportions in the production of commodities, consumers would have an incentive to substitute the former for the latter if the price of their time, measured, say, by their potential real wage rate, declined. Since the incidence of unemployment causes the price of time to fall, one would expect unemployed workers to substitute their own time for market goods in the production of commodities.

In this note, I use the notion of substitution in production between goods and time to interpret data on detailed family consumption expenditures before and during unemployment. The information is contained in a survey of the insured unemployed. In particular, I focus on differences in the pattern of expenditure reductions that emerge when primary market workers are unemployed, compared to when secondary market workers are unemployed. I also examine differences in the estimated income elasticity of total consumption for claimants in low unemployment areas compared to that for claimants in high unemployment areas. A tentative part of this analysis is a computation of the reduction in total consumption due to substitution of time for goods that would occur if unemployment were fully anticipated and, hence, not accompanied by a reduction in permanent income.

I. Data and Methods

This note is based on data from six studies of the insured unemployed, conducted by the Bureau of Employment Security (*BES*) of the U.S. Department of Labor between 1953 and 1958.[1] The labor market areas in the *BES* sample, the dates during which each survey was conducted, and the overall unemployment rate of the area during those dates are shown in Table 1. The surveys included average monthly family expenditures before and during unemployment for eleven exhaustive components of total consumption. Data were collected from three types of claimants: single individuals, heads of four person households (primary market workers), and nonheads of four person households (secondary market workers).[2] There were 462 single individuals in the sample, 774 heads of four person households, and 482 nonheads. In the *BES* publication based on the surveys, the expenditure information was given in the form of area averages by claimant type. Hence, there were six observations for each claimant type.

I deflated outlays in each expenditure category by a corresponding component of the Consumer Price Index (*CPI*) (1957—59 = 100). I selected the appropriate annual deflators for before- and during-unemployment expenditures as follows. For Pittsburgh, the unemployment period occurred mainly during 1954. Therefore, deflation of outlays during this period made use of the 1954 *CPI* components. The deflators used with before-unemployment spending were chosen by applying the average duration of unemploy-

* Research associate, National Bureau of Economic Research. I am grateful to Gary S. Becker, Carol Breckner, Ilene J. Grossman, Arlene Liebowitz, Robert T. Michael, Margaret Reid, Paul Wachtel, an anonymous referee, and the editor of this *Review* for their helpful comments on an earlier draft.

[1] For a complete description of the data, see *BES* No. U-203. Note that the *BES* is now part of the Manpower Administration.

[2] Although the published data did not give the sex of the claimant, most nonheads of four person households are undoubtedly wives. Since differences in the economic roles of primary and secondary market workers in the household can explain my main results, I do not emphasize differences based on a sex classification in the paper. I would like to thank Carol Breckner, Ilene J. Grossman, and a referee for urging me to adopt the primary worker-secondary worker terminology. This terminology should prevent readers from getting the mistaken impression that I am a "male chauvinist pig."

TABLE 1—THE *BES* SURVEY

Area	Dates	Unemployment Rate (percent)
Pittsburgh, Pennsylvania	9/53–8/54	9.4
Tampa-St. Petersburg, Florida	11/55–10/56	4.2
Andersonville-Greenville-Spartanburg, South Carolina	4/56–3/57	3.7
Albany-Schenectady-Troy, New York	5/56–4/57	3.4
Portland, Oregon	4/57–3/58	10.0
St. Louis, Missouri	4/57–3/58	9.2

ment to the midpoint date of the survey period. For Pittsburgh, the midpoint date was February 15, 1954. Since claimants reported an average duration of unemployment of 20 months, it was assumed to begin in June 1952, and outlays while employed were deflated by the *CPI* components for 1952. A similar procedure was applied to the expenditure data of claimants in the other five areas.

After deflation, I computed mean expenditures before and during unemployment by claimant type. The mean expenditure on a given item was defined as a weighted average of the six area means, where the weights were the proportion of the sample in each area. Note that my procedure eliminated the effects on the expenditure data of price changes both during the entire 1953–58 period and during the movement from employment to unemployment in each area.

II. Differences in Head-Nonhead Expenditure Reductions

Table 2 gives consumption elasticities and marginal propensities to consume for four person families in which the head was unemployed, and for four person families in which the nonhead was unemployed. The consumption elasticity of food, for example, equals the percentage reduction in deflated family food outlays caused by unemployment divided by the percentage reduction in deflated total consumption. The marginal propensity to consume food equals the absolute reduction in deflated food outlays divided by the absolute reduction in deflated total consumption.

In comparing families in which the head was unemployed to those in which the nonhead was unemployed, I use the reduction in current consumption as an index of the reduction in permanent income due to unemployment. The reduction in current consumption is used instead of the reduction in current income because the former clearly has a smaller transitory component than the latter. Since to a large extent, unemployment causes a temporary decline in income, one

TABLE 2—CONSUMPTION ELASTICITIES AND MARGINAL PROPENSITIES TO CONSUME FOR FOUR PERSON HOUSEHOLDS WHERE HEAD OR NONHEAD IS UNEMPLOYED

	Consumption Elasticity		Marginal Propensity to Consume	
Item	Head	Nonhead	Head	Nonhead
Food	.74	.74	.22	.20
Housing and utilities	.79	.35	.17	.07

would expect persons to react to it mainly by adjusting their savings.[3]

According to traditional demand theory, the various goods and services in Table 2 are the basic arguments in consumers' utility functions. Provided relative prices did not change when workers became unemployed, it would attribute reductions in the consumption of these goods and services solely to an income effect. If families in which the head was unemployed had the same set of permanent income or consumption elasticities as families in which the nonhead was unemployed, then the correlation coefficient between these two sets of elasticities should equal +1. In fact, the Spearman rank correlation coefficient between the consumption elasticities in Table 2 is −.23, and the product-moment correlation coefficient is −.04.[4] Such low (and even negative) correlations are inconsistent, at least at first glance, with the hypothesis that the two claimant groups have the same set of permanent income elasticities.

Some of the differences in the pattern of expenditure reductions revealed by Table 2 are striking. Whether the dissimilarity between the two consumption elasticities for each item in the table is measured by their ratio or by their difference, household operations and clothing deserve special mention. Their consumption elasticities for families in which the nonhead was unemployed are, respectively, four times as large and one and a half times as large as the corresponding elasticities for families in which the head was unemployed. In terms of marginal propensities to consume, the differential impact of unemployment of heads and nonheads on the quantity of household operations demanded is most noticeable. The reduction in household operations for nonheads accounts for 27 percent of the reduction in total consumption. The corresponding figure for heads is 5 percent.[5]

The household production function approach to demand analysis provides a cogent explanation of the relatively large reductions in the quantities of household operations and clothing demanded when secondary market workers become unemployed. Its explanation is based on the proposition that the elasticities of derived demand for various market goods with respect to the price of secondary workers' time are likely to exceed the elasticities with respect to the price of primary workers' time.

For instance, the specific items included in household operations outlays are inputs, together with primary workers' time and secondary workers' time, into the production of commodities such as "cleanliness of the home," "cleanliness of the people who live in the home," and "child care."[6] When either primary workers or secondary workers become unemployed, the price of their time falls, and an incentive is created to substitute this time for market goods in the production of cleanliness or child care. Since secondary market workers are primary nonmarket workers, the share of their time in the total cost of producing certain commodities is likely to exceed the share of primary workers' time in total cost. Thus, if the Allen partial elasticities of substitution in production (see R. G. D. Allen, pp. 503–09) between primary workers' time and market goods and between secondary market workers' time and market goods were equal, the derived demand elasticity of household operations with respect to the price of secondary workers' time would be greater.[7] To the extent that the secondary

[3] If the permanent income elasticity of total consumption equaled unity, then the percentage change in consumption would coincide with the percentage change in permanent income.

[4] If the category Other Consumption is omitted from these calculations, the rank correlation coefficient is +.02, and the product-moment correlation coefficient is +.12.

[5] Although the consumption elasticity of personal care is 1.4 for nonheads and 0 for heads, the differential impact of unemployment of heads and nonheads on the quantity of this item demanded falls dramatically when marginal propensities to consume are examined.

[6] Household operations outlays consist of 1) laundry sent out, 2) cleaning of rugs and draperies, 3) launderette and coin operated washing machine service, 4) wages and tips to domestic servants, 5) laundry soaps and cleaning supplies, and 6) fees to day nurseries, child care centers, and baby sitters.

[7] In analyzing derived demand elasticities, I rule out substitution in consumption among commodities by as-

worker partial elasticity of substitution exceeded the primary worker partial elasticity of substitution, the difference in derived demand elasticities would be even larger.

Along similar lines, clothing and time produce commodities such as "warmth" and "style." Once again, the results in Table 2 are consistent with the hypothesis of a positive differential between the shares of secondary and primary workers' time in total cost. Presumably, in some household activities, there are negative differentials between these shares or greater partial elasticities of substitution between primary workers' time and market goods. Indeed, for the items housing and utilities, other consumption, and medical care, head consumption elasticities and marginal propensities to consume exceed the corresponding nonhead estimates. The first two items, however, consist of diverse components, and the medical care differential can be explained by the purchase of group health insurance by the head for himself and his family at his place of work. Therefore, it is not possible to use the *BES* budget studies to identify household activities in which primary workers' time and market goods are good substitutes.

It should be noted that within the context of the household production function model, the low correlation between the consumption elasticities of heads and nonheads need not imply that the two groups have different "pure" permanent income elasticities. By pure permanent income elasticity, I mean the income elasticity that would be observed if a change in permanent income were not accompanied by a change in the value of the time of one or more family members. This would occur if, for example, a family, all of whose members worked in the market, suffered an unanticipated decline in property income. Since unemployment lowers the value of time, it generates substitution as well as income effects. These substitution effects can go a long way in explaining the differential impact of the unemployment of primary market workers and secondary market workers on the quantities of various market goods demanded.

III. Income Elasticities of Total Consumption

Three of the *BES* studies were undertaken during years of business contraction, while the other three were conducted during years of relative prosperity (see Table 1). The three labor market areas that were surveyed during recessions had much higher unemployment rates than the other three. In this section, I compare the income elasticity of total consumption for claimants in high unemployment areas to that for claimants in low unemployment areas. Presumably, claimants in high unemployment areas were unemployed mainly for cyclical reasons. On the other hand, unemployment in the other areas was presumably due to seasonal or frictional factors.[8]

In general, it is much more difficult for workers to predict or anticipate cyclical unemployment than to predict seasonal or frictional unemployment. Hence, they would view a loss in income due to the former type of unemployment as a more serious loss than that due to the latter type. Based on this argument, unemployed workers in high unemployment areas should exhibit larger income elasticities of total consumption than those in low unemployment areas. Table 3 illustrates the truth of this proposition. For each of the three claimant types, the estimated income elasticity of consumption in high unemployment areas is approximately twice as large as the income elasticity in low unemployment areas.[9]

suming that *relative* prices of commodities are not affected by changes in the price of time. In other words, I assume that the shares of secondary and primary workers' time in the total cost of producing a given commodity do not vary among commodities. Given the fairly aggregate nature of the items in Table 2, this is a weak assumption.

[8] Since all of the members of the sample were receiving unemployment compensation benefits, it is not likely that they were unemployed for long-term or structural reasons.

[9] The income elasticity of total consumption equals the percentage reduction in deflated family consumption due to unemployment divided by the percentage reduction in deflated family income. Note that family income during unemployment includes unemployment compensation benefits.

TABLE 3—INCOME ELASTICITIES OF TOTAL CONSUMPTION BY CLAIMANT TYPE AND UNEMPLOYMENT LEVEL OF AREA

Group	Income Elasticity
Single individuals	
High unemployment areas	.38
Low unemployment areas	.23
Heads of four person households	
High unemployment areas	.46
Low unemployment areas	.20
Nonheads of four person households	
High unemployment areas	.43
Low unemployment areas	.18

If seasonal or frictional unemployment were fully anticipated, it would cause no reduction in permanent income. This does not mean that such unemployment would have no impact on consumption. The price of time of seasonally unemployed workers would decline temporarily, and they would have an incentive to substitute time for goods in the production of commodities.[10]

By assuming that workers in low unemployment areas fully anticipated their unemployment, it is possible to put an upper limit on the reduction in consumption due to substitution of time for goods. If the income elasticity for heads is employed in this calculation, then a 10 percent reduction in family income due to fully anticipated unemployment would reduce consumption by 2 percent on account of the substitution effect. Put differently, the income elasticity for heads in high unemployment areas shows that if family income fell by 10 percent in a recession, consumption would fall by 4.6 percent. A little less than half of this decline would be due to the substitution of time for goods, and a little more than half would be due to the reduction in permanent income. It should be emphasized that this is an extremely tentative calculation. To the extent that workers in low unemployment areas did not anticipate their unemployment, part of their reduction in consumption would be due to an income effect. I believe, however, that the incentive to substitute time for goods during periods of unemployment can explain at least part of the decline in total consumption during such periods.

[10] This point has been made by Becker and Gilbert R. Ghez. Note from Table 3 that with the level of unemployment held constant, income elasticities are practically the same for each of the three types of claimants. Therefore, there is no evidence in the *BES* data that secondary market workers' time and market goods are better substitutes in *all* household activities than primary market workers' time and market goods.

IV. Summary and Implications

In this note, I have argued that in the production of the household commodities, cleanliness child care, warmth, and style, secondary market workers' time and market goods are better substitutes than primary market workers' time and market goods. This explains the relatively large declines in outlays on household operations and clothing that are observed when secondary workers become unemployed. During recent decades, the labor force participation rates of married women and other secondary market workers have increased substantially. Therefore, an immediate implication of my findings is that the pattern of cyclical fluctuations in the various components of total consumption might change in the future. Given the relatively high elasticities of derived demand for various market goods with respect to changes in the price of secondary market workers' time, cyclical fluctuations in household operations and in clothing should increase in the future.

In this note, I have also argued that not all of the reduction in total consumption that accompanies unemployment can be attributed to an income effect. Instead, part of this reduction is due to the incentive to substitute time for goods in the production of commodities. Hence, even if unemployment compensation benefits offset a substantial fraction of any decline in permanent income caused by unemployment, one would expect total consumption to fall during such periods.

A Test for Relative Economic Efficiency: Some Further Results

By Pan A. Yotopoulos and Lawrence J. Lau*

Economic efficiency can be decomposed into two components: technical efficiency and price efficiency. A firm is said to be more technically efficient than another if it consistently produces larger quantities of output from the same quantities of measurable inputs. Differences in technical efficiency among (groups of) firms can therefore be captured by quantifying their differences in "technology."[1] On the other hand, a firm is said to be price-efficient if it maximizes profits. Since profit maximization implies equalization of the value of the marginal product of each variable input to its price, analysis of price efficiency involves also variables that are not ordinarily included in production function analysis—prices.[2] Differences in economic efficiency among (groups of) firms may be caused by differences in technical and/or price efficiency.

We compare relative economic efficiency of two firms with varying degrees of technical and price efficiency. For this purpose we compare the actual profit functions of the two firms, at given output and input prices and quantities of measurable fixed inputs. The firm which has higher profits (i.e., total revenue minus the total cost of the variable factors of production) within a certain specified range of output and input prices is considered to be the more economic-efficient firm (within that range of prices). By applying this concept in the comparison of small and large Indian farms, we found in our previous paper (see Lau and Yotopoulos (1971)) that small farms are more economic-efficient. For many purposes, however, it is important to assess the relative importance of the two factors responsible for observable differences in relative economic efficiency. In this paper, we extend our earlier work with the specific purpose of identifying and isolating the causes for such difference between small and large farms. As an illustration we apply our technique to the same body of data as used in Lau and Yotopoulos (1971).

Knowledge of the values of the technical- and price-efficiency parameters may be crucial in the formulation of policies. Suppose that differences in relative economic efficiency stem from differences in behavioral decision rules associated with the ability to maximize profits, then identifying the two components of technical and price efficiency can lead to better predictions. Again, suppose it were socially desirable to bring about the "value of the marginal product equals cost" rule, it would be possible, if the actual decision rules are known, to work out a system of ad valorem taxes and subsidies on the variable inputs and lump sum taxes and subsidies so that the social optimum would be attained. Finally, such knowledge may have important implications on agrarian reform, agricultural education, and agricultural extension policies.

As a by-product of our analysis we also perform a simple statistical test of the hypothesis of constant returns to scale within the framework of the profit function. In our specific application the question of whether agriculture is characterized by increasing returns, constant, or decreasing returns is a

* Associate professor, Food Research Institute, and assistant professor, department of economics, Stanford University, respectively. Earlier drafts of this paper benefitted from comments of Richard R. Nelson and Vernon W. Ruttan. Wuu-Long Lin provided competent research assistance. The research was partially supported by National Science Foundation grant GS-2874-A1 to Stanford University. We alone are responsible for any errors therein.

[1] Examples of studies that focus on technical efficiency are Michael Farrell, Yair Mundlak, W. D. Seitz (1970), Robert Solow, and C. Peter Timmer (1970).

[2] Examples of studies of price efficiency are W. David Hopper, Theodore W. Schultz, and Yotopoulos (1967a, 1968). These studies, however, are more limited than our approach to price efficiency since they allow only for inter-group (instead of both inter- and intra-group) variations in factor prices. The difference is further spelled out in J. Wise and Yotopoulos (1969).

crucial point that has important policy implications.

In Section I, the model is briefly described. In Section II, the relevant statistical tests are formulated in the context of the Cobb-Douglas function. Section III is on empirical implementation and statistical results. Section IV contains a brief summary and conclusions.

I. The Model

The model that we use is identical to the one in Lau and Yotopoulos (1972). The basic extension that allows us to identify separately the components of technical and price efficiency lies in the utilization of the factor demand functions. Let there be two firms[3] denoted by the superscripts, with the production functions, respectively,[4]

$$(1)\quad V^1 = A^1F(X^1, Z^1);\; V^2 = A^2F(X^2, Z^2)$$

where V is output, X and Z are vectors representing the variable inputs and the fixed inputs of production, respectively. Equation (1) incorporates firm-specific technical efficiency,[5] captured by the neutral differences in the production function, A^1 and A^2. Two firms are equally technical-efficient if, and only if, $A^1=A^2$.

The marginal conditions are given by

$$(2)\quad \begin{aligned} &\frac{\partial A^1F(X^1, Z^1)}{\partial X_j^1} = k_j^1 c_j^1 \\ &k_j^1 \geqq 0 \\ &\frac{\partial A^2F(X^2, Z^2)}{\partial X_j^2} = k_j^2 c_j^2 \\ &k_j^2 \geqq 0; \\ &j = 1, \ldots, m \end{aligned}$$

where c_j^i is the money price of the jth input divided by the money price of output faced by the ith firm. The c_j^i's will be referred to as normalized prices. Equation (2) allows a firm to be unsuccessful in its attempts to equate values of the marginal product of its inputs to their respective normalized prices. This is introduced through the firm-specific and variable input-specific k_j^i and it represents differences in managerial-entrepreneurial ability. If, and only if, two firms are equally price-efficient with respect to all variable inputs, then $k_j^1=k_j^2$, for $j=1, \ldots, m$.[6]

To the production function $F(X, Z)$ corresponds a Unit-Output-Price (UOP) profit function,[7]

$$(3)\quad \Pi = G(c_1, \ldots, c_m; Z_1, \ldots, Z_n)$$

where Π is UOP profit (i.e., current revenues less current total variable costs) divided by the money price of output and c_j is the normalized price of variable input X_j. As shown in our 1971 article, the actual demand functions are given by

$$(4)\quad X_j^i = \frac{-A^i}{k_j^i}\,\frac{\partial G(k^ic^i/A^i; Z^i)}{\partial c_j^i},\qquad i = 1, 2; j = 1, \ldots, m$$

The supply function is given by

$$(5)\quad V^i = A^i\left(G(k^ic^i/A^i; Z^i) - \sum_{j=1}^{m} c_j^i\,\frac{\partial G(k^ic^i/A^i; Z^i)}{\partial c_j^i}\right)\qquad i = 1, 2; j = 1, \ldots, m$$

[3] This analysis can be easily extended to n firms.

[4] In the notation that follows, we will continue at times to use the variables X, Z, k, and c unsubscripted in order to denote vectors.

[5] Consistent with the "technical progress" literature, these parameters represent differences in environmental factors, in engineering entrepreneurial ability and in other nonmeasurable fixed factors of production.

[6] In our formulation, k_j reflect a general systematic rule of behavior—a decision rule that gives the profit-maximizing marginal productivity conditions as a special case. That the decision rule for the firm consists of equating the marginal product to a constant times the normalized price of each input may be rationalized as follows: (i) Consistent over- or under-valuation of the opportunity costs of the resources by the firm; (ii) Satisficing behavior; (iii) Divergence of expected and actual normalized prices; (iv) Divergence of the subjective probability distribution of the normalized prices from the objective distribution of normalized prices; (v) The elements of k^i may be interpreted as the first-order coefficients of a Taylor's series expansion of arbitrary decision rules of the type (over)

From the actual supply and demand functions, we can obtain the *actual UOP profit function*,

$$(6)\quad \Pi_a^i = V^i - \sum_{j=1}^{m} c_j^i X_j^i = A^i\left(G(k^i c^i/A^i; Z^i) + \sum_{i=1}^{m} \cdot \frac{(1-k_j^i)}{k_j^i}\frac{\partial G(k^i c^i/A^i; Z^i)}{\partial c_j^i}\right), \quad i = 1, 2; j = 1, \ldots, m$$

Note that even if there exists no difference in technical efficiency (i.e., the A^i), there may be more than one set of k^i's that correspond to the same actual UOP profit function.

It should be emphasized at this point that X_j^i, V^i, and Π_a^i as given in (4), (5), and (6) are the actual quantities of inputs demanded, output supplied, and UOP profits received by firm i given the firm-specific A^i and the firm- and input-specific k_j^i. When appropriate functional forms are specified for G in equation (3), then equations (4)–(6) may be derived and estimated. Note that because of the profit identity only $(m+1)$ of the $(m+2)$ equations in (4), (5), and (6) are independent. Hence only $(m+1)$ of the functions need be estimated.

Observe that: (i) $\partial\Pi_a^i/\partial A^i > 0$, i.e., actual profit always increases with the level of technical efficiency for given normalized input prices and k^i; (ii) When $k_j^i = 1$ for $j=1, \ldots, m$, the firm is a true profit maximizer; (iii) If, and only if, $A^1 = A^2$ *and* $k^1 = k^2$ the actual UOP profit functions and the demand functions of the two firms coincide with each other. From these observations a number of tests for relative economic efficiency become possible.

First, one can test the null hypothesis of equal relative economic efficiency. This hypothesis is equivalent to testing whether there exists significant differences between the profit functions. Such a test has been carried out in our 1971 article, in which the hypothesis of equal relative economic efficiency is rejected.

Second, it is possible to test separately the hypotheses of equal technical efficiency, i.e., $A^1 = A^2$, and of equal price efficiency, i.e., $k^1 = k^2$, or both. Note that one can have equal relative economic efficiency without necessarily having both $A^1 = A^2$ and $k^1 = k^2$. Finally, one can compute A^i and k^i explicitly to isolate the sources of differences in economic efficiency. These are the specific tasks of this paper.

II. The Formulation of the Cobb-Douglas Case

A Cobb-Douglas production function with decreasing returns in the m variable inputs and with n fixed inputs is given by[8]

$$V = A \prod_{j=1}^{m} X_j^{\alpha_j} \prod_{j=1}^{n} Z_j^{\beta_j}$$

where

$$\mu \equiv \sum_{j=1}^{m} \alpha_j < 1$$

The UOP profit function for this Cobb-Douglas production function is

$$(7)\quad \Pi^* = A^{(1-\mu)^{-1}}(1-\mu) \cdot \left(\prod_{j=1}^{m}\left(\frac{c_j}{\alpha_j}\right)^{-\alpha_j(1-\mu)^{-1}}\right) \cdot \left(\sum_{j=1}^{n} Z_j^{\beta_j(1-\mu)^{-1}}\right)$$

By direct computation, the actual UOP profit function for this Cobb-Douglas production function for firm i, with efficiency parameters A^i and k^i is

$$\Pi_a^i = A^{i(1-\mu)^{-1}}\left(1 - \sum_{j=1}^{m} \alpha_j/k_j^i\right) \cdot \left(\prod_{j=1}^{m} (k_j^i)^{-\alpha_j(1-\mu)^{-1}}\right) \cdot \left(\prod_{j=1}^{m} \alpha_j^{\alpha_j(1-\mu)^{-1}}\right)$$

$$\frac{\partial F}{\partial X_j^i} = f_j^i(c_j^i), \qquad i = 1, 2,$$

where $f_j^i(0) = 0$ and $f_j^{i\prime}(c_j^i) \geq 0$. A wide class of decision rules may be encompassed under this formulation.

[7] For a more detailed discussion of these derivations, see our 1971 article.

[8] The value of $\mu < 1$ is required since constant or increasing returns in the variable inputs are inconsistent with profit maximization.

$$\cdot\left(\prod_{j=1}^{m}(\overset{i}{c_j})^{-\alpha_j(1-\mu)^{-1}}\right)$$

$$\cdot\left(\prod_{j=1}^{n}(\overset{i}{Z_j})^{\beta_j(1-\mu)^{-1}}\right) \qquad i=1,2$$

or

$$\text{(8)}\quad \overset{i}{\Pi_a} = \overset{i}{A_*}\left[\prod_{j=1}^{m}(\overset{i}{c_j})^{\alpha_j^*}\right]\left[\prod_{j=1}^{n}(\overset{i}{Z_j})^{\beta_j^*}\right] \qquad i=1,2$$

where

$$\overset{i}{A_*} \equiv \overset{i}{A}^{(1-\mu)^{-1}}\left(1-\sum_{j=1}^{m}\alpha_i/\overset{i}{k_j}\right)$$

$$\cdot\left(\prod_{j=1}^{m}(\overset{i}{k_j})^{-\alpha_j(1-\mu)^{-1}}\right)$$

$$\cdot\left(\prod_{j=1}^{m}\alpha_j^{\alpha_j(1-\mu)^{-1}}\right) \qquad i=1,2$$

$$\text{(9)}\quad \overset{i}{k_*} \equiv \left(1-\sum_{j=1}^{m}\alpha_j/\overset{i}{k_j}\right)(1-\mu)^{-1} \qquad i=1,2$$

$$\overset{*}{\alpha_j} \equiv -\alpha_j(1-\mu)^{-1} < 0 \qquad j=1,\ldots,m$$

$$\overset{*}{\beta_j} \equiv \beta_j(1-\mu)^{-1} > 0 \qquad j=1,\ldots,n$$

Similarly by direct computation the demand functions for variable inputs are given by

$$\overset{i}{X_l} = \overset{i}{A}^{(1-\mu)-1}(\alpha_l/\overset{i}{k_l}\overset{i}{c_l})\left(\sum_{j=1}^{m}(\overset{i}{k_j})^{-\alpha_j(1-\mu)^{-1}}\right)$$

$$\cdot\left(\prod_{j=1}^{m}(\alpha_j)^{\alpha_j(1-\mu)^{-1}}\right)\left(\prod_{j=1}^{m}(\overset{i}{c_j})^{-\alpha_j(1-\mu)^{-1}}\right)$$

$$\cdot\left(\prod_{j=1}^{n}(\overset{i}{Z_j})^{\beta_j(1-\mu)^{-1}}\right) \qquad i=1,2;\quad l=1,\ldots,m$$

$$\text{(10)}\quad \overset{i}{X_l} = -\overset{i}{A_*}\overset{*}{\alpha_l}(\overset{i}{k_l})^{-1}(\overset{i}{c_l})^{-1}(\overset{i}{k_*})^{-1}$$

$$\cdot\left(\prod_{j=1}^{m}(\overset{i}{c_j})^{\alpha_j^*}\right)\left(\prod_{j=1}^{n}(\overset{i}{Z_j})^{\beta_j^*}\right) \qquad i=1,2;\quad l=1,\ldots,m$$

or, by substitution from equation (8)

$$\text{(11)}\quad \frac{-\overset{i}{c_l}\overset{i}{X_l}}{\overset{i}{\Pi_a}} = (\overset{i}{k_l})^{-1}(\overset{i}{k_*})^{-1}\overset{*}{\alpha_l} \equiv \overset{*i}{\alpha_l} \qquad i=1,2;\quad l=1,\ldots,m$$

Equation (8) indicates that the actual *UOP* profit functions of the two firms differ by a constant factor, which is a function of k_j^i and A^i. In addition, from equation (11) all the demand functions differ across firms by constant factors. The basic estimating equations for this study are (8) after taking natural logarithms, and (11).

The first hypothesis we can investigate within our framework is that of equal relative economic efficiency. This implies that

$$\text{(12)}\quad \overset{1}{A_*} = \overset{2}{A_*}$$

or that $ln\ (A_*^1/A_*^2)=0$. Note that it is possible for two firms to be equally economic-efficient without being equally technical-efficient or equally price-efficient or both. We note, moreover, that if, and only if, $A^1=A^2$ *and* $k^1=k^2$, then $A_*^1=A_*^2$ *and* $\alpha_l^{*1}=\alpha_l^{*2}$, $l=1,\ldots,m$ and the two functions Π_a^1 and Π_a^2 (or $ln\ \Pi_a^1$ and $ln\ \Pi_a^2$) should be identical. This implies the following linear relations:

$$\text{(13)}\quad \text{(i)}\ \overset{1}{A_*} = \overset{2}{A_*} \quad \textit{and}$$

$$\text{(ii)}\ \overset{*1}{\alpha_l} = \overset{*2}{\alpha_l}, \qquad l=1,\ldots,m$$

We can therefore test for the two components of economic efficiency, i.e., for equal *relative technical* and *price efficiency* by testing statistically the joint hypotheses in (13). Furthermore, we observe that if, and only if, $k^1=k^2$, then

$$\text{(14)}\quad \overset{*1}{\alpha_l} = \overset{*2}{\alpha_l}, \qquad l=1,\ldots,m$$

Hence a test of equal *relative price efficiency* (but not equal economic efficiency) consists of testing the joint hypotheses in (14).

In our model we may also investigate the *absolute price efficiency* hypothesis, i.e., whether one or both firms have maximized

profits subject to given prices. Observe that perfect profit maximization in the ith firm or group of firms implies

$$(15) \quad \text{(i) } k_l^i = 1 \qquad l = 1, \ldots, m \quad \text{and}$$

$$\text{(ii) } k_*^i = 1$$

From (15) it follows that

$$(16) \qquad \overset{*i}{\alpha_l} = \overset{*}{\alpha_l}, \qquad l = 1, \ldots, m$$

This furnishes a necessary and sufficient statistical test of the hypothesis of profit maximization.[9]

Next we turn our attention to the question of the degree of returns to scale. For the case of a Cobb-Douglas profit function, the necessary and sufficient condition for homogenity of degree k of the underlying production function is [10]

$$\frac{(k-1)}{k}\sum_{j=1}^{m}\overset{*}{\alpha_j} + \frac{1}{k}\sum_{j=1}^{n}\overset{*}{\beta_j} = 1$$

or alternatively,

$$\sum_{j=1}^{n}\overset{*}{\beta_j} = k - (k-1)\sum_{j=1}^{m}\overset{*}{\alpha_j}$$

[9] To see that (16) implies (15), and hence is a necessary and sufficient condition for profit maximization for firm i, just observe that (16) implies

$$k_l^{i-1} k_*^{i-1} = 1, \qquad l = 1, \ldots, m$$

which in turn implies that

$$k_l^{i-1} = k_{l'}^{i-1}, \qquad l, l' = 1, \ldots, m$$

Hence

$$k_l^{i-1} = k_*^i = \frac{\left(1 - k_l^{i-1}\sum_{j=1}^{m}\alpha_j\right)}{\left(1 - \sum_{j=1}^{m}\alpha_j\right)}$$

which leads to

$$k_l^{i-1} = 1 \qquad l = 1, \ldots, m$$

Equation (16) therefore furnishes a strong statistical test of the hypothesis of profit maximization.

[10] This result is derived in Lau (1972) and Lau and Yotopoulos (1972).

Note that $\sum_{j=1}^{m}\alpha_j^* < 0$ by the monotonicity conditions on the profit function. Hence, if $k > 1$ (increasing returns), $\sum_{j=1}^{n}\beta_j^* > 1$. If $k = 1$ (constant returns), $\sum_{j=1}^{n}\beta_j^* = 1$. If $k < 1$ (decreasing returns), $\sum_{j=1}^{n}\beta_j^* < 1$. A test of the hypothesis of constant returns *in all inputs* in the Cobb-Douglas case then becomes a test of the hypothesis $\sum_{j=1}^{n}\beta_j^* = 1$, where β_j^* are the elasticities of the profit function with respect to the fixed factors of production. We shall test this hypothesis in our application.

Finally, based on the definitional identities in equations (9) and (11) and the estimates of $ln\ A_*^i$, α_j^*, β_j^*, and α_l^{*i}, one can compute the values of A^i and the k^i, as well as the direct production elasticities of the inputs α_j and β_j.

III. Empirical Analysis

In this section we use the same data as used in our 1971 article from the *Studies in the Economics of Farm Management* (*The Studies*) of the Indian Ministry of Food and Agriculture to estimate jointly the *UOP* profit function and the labor demand function conditional on the given quantities of cultivable land and fixed capital.[11]

The profit function (8) and the labor demand function (11) may be written

$$(17) \quad ln\,\Pi_a = ln\,\overset{S}{A_*} + \overset{*}{\delta_L} D_L + \overset{*}{\alpha_1}\, ln\, w + \overset{*}{\beta_1}\, ln\, K + \overset{*}{\beta_2}\, ln\, T$$

$$(18) \quad \frac{-wL}{\Pi_a} = \overset{*L}{\alpha_1} D_L + \overset{*S}{\alpha_1} D_S$$

where Π_a is actual *UOP* profit (total revenue less total variable cost, divided by the price of output), w is normalized wage rate, K is interest on fixed capital, T is cultivable land, $\delta_L \equiv ln\,(A_*^L/A_*^S)$, and D_L and D_S are dummy variables taking the value of one for large and small farms, respectively, and zero otherwise. Large farms are defined as those with cultivable land greater than ten acres per farm. A maintained hypothesis is that the production function is identical on large and

[11] A description of the data is available in our 1971 article. We shall not repeat it here.

small farms up to a neutral efficiency parameter. This implies that the coefficients corresponding to $ln\ w$, $ln\ K$, and $ln\ T$ are identical for large and small farms. A problem arises at this point. Our formulation of the *UOP* profit and labor demand functions is in terms of normalized prices. However, in our empirical application normalized prices are not available since the data on prices of output are rather poor. Fortunately, we note that (17) may be rewritten

$$\begin{aligned} ln\ \Pi_a &= ln\ \Pi' - ln\ p \\ &= ln\ A_*^S + \overset{*}{\delta}_L D_L + \overset{*}{\alpha}_1\ ln\ w' - \overset{*}{\alpha}_1\ ln\ p \\ &\quad + \overset{*}{\beta}_1\ ln\ K + \overset{*}{\beta}_2\ ln\ T \end{aligned}$$

or

$$\begin{aligned} ln\ \Pi' &= ln\ A_*^S + \overset{*}{\delta}_L D_L + (1 - \overset{*}{\alpha})\ ln\ p \\ &\quad + \overset{*}{\alpha}_1\ ln\ w' + \overset{*}{\beta}_1\ ln\ K + \overset{*}{\beta}_2\ ln\ T \end{aligned}$$

where Π' is actual money profit in rupees, w' is the money wage rate in rupees per day, and p is the price of the output in rupees. If the prices of outputs differ only across states, then one can insert state dummy variables to capture the effect of differences due to $(1-\alpha_1^*)\ ln\ p$. This also allows interstate differences in the technical efficiency parameters. Observe that (18) holds independently of the price of output

$$-\frac{wL}{\Pi_a} = -\frac{w'L}{\Pi'} = \alpha_1^{*L} D_L + \alpha_1^{*S} D_S$$

Hence our final estimating equations consist of

$$\text{(19)}\quad \begin{aligned} ln\ \Pi' &= ln\ A_*^S + \overset{*}{\delta}_L D_L + \sum_{i=1}^{4} \overset{*}{\delta}_i D_i \\ &\quad + \overset{*}{\alpha}_1\ ln\ w' + \overset{*}{\beta}_1\ ln\ K \\ &\quad + \overset{*}{\beta}_2\ ln\ T \end{aligned}$$

and

$$\text{(20)}\quad -\frac{w'L}{\Pi'} = \alpha_1^{*L} D_L + \alpha_1^{*S} D_S$$

where Π' is farm profit in rupees and w' is money wage rate.

A remark about the stochastic specification of the model is appropriate at this point. Not much is known about how disturbance terms in general should be introduced into economic relationships although Irving Hoch (1955, 1958) and Mundlak and Hoch and subsequently Arnold Zellner, Jan Kmenta and Jacques Drèze have proposed one possible assumption that is workable in the Cobb-Douglas case. Here we follow the usual, and admittedly *ad hoc* practice of assuming an additive error with zero expectation and finite variance for each of the equations (19) and (20).[12] For the same farm, the covariance of the errors of the two equations is permitted to be nonzero. However, the covariances of the errors of either equation corresponding to different farms are assumed to be identically zero.

Given this specification of errors, it is immediately apparent that Zellner's method provides an asymptotically efficient method of estimation. Moreover, the efficiency of estimation can be increased by imposing known constraints on the coefficients in the equations.

Six statistical hypotheses are tested successively on the data. The results of these tests are reported in Table 1. They are:

(i) Equal Relative Economic Efficiency

$$H_0: \overset{*}{\delta}_L = 0$$

i.e., $A_*^L = A_*^S$ or $ln\ (A_*^L/A_*^S) = 0$. This hypothesis is rejected at the 10 percent significance level. Hence we conclude that small farms are relatively more economic-efficient than large farms.

(ii) Equal Relative Price Efficiency

$$H_0: \alpha_1^{*L} = \alpha_1^{*S}$$

This is not rejected at the 10 percent level. Hence we conclude that small and large

[12] Marc Nerlove, in his pioneering study of cost functions, derives an additive error to the natural logarithm of the cost function. We can do the same here for our profit function, using the same assumptions as his. The additive error in the second equation may arise from different abilities to maximize profits or divergence between expected and realized prices.

TABLE 1—STATISTICAL HYPOTHESES TESTED

Maintained Hypothesis	Tested Hypothesis H_0	Computed F	Critical $F_{0.10}$
	i) $\delta_L^* = 0$	$F(1, 57) = 3.96$	$F(1, 57) = 2.79$
	ii) $\alpha_1^{*L} = \alpha_1^{*S}$	$F(1, 57) = 1.93$	$F(1, 57) = 2.79$
	iii) $\delta_L^* = 0$, $\alpha_1^{*L} = \alpha_1^{*S}$	$F(2, 57) = 4.19$	$F(2, 57) = 2.39$
$\alpha_1^{*L} = \alpha_1^{*S}$	iv) $\alpha_1^{*S} = \alpha_1^{*}$	$F(1, 58) = 0.09$	$F(1, 58) = 2.79$
$\alpha_1^{*L} = \alpha_1^{*S}$	v) $\alpha_1^{*L} = \alpha_1^{*}$	$F(1, 58) = 0.09$	$F(1, 58) = 2.79$
$\left.\begin{array}{l}\alpha_1^{*L} = \alpha_1^{*} \\ \alpha_1^{*S} = \alpha_1^{*}\end{array}\right\}$	vi) $\beta_1^* + \beta_2^* = 1$	$F(1, 59) = 2.01$	$F(1, 59) = 2.79$

Note: For definition of variable see Table 2.
Source: Table 2.

farms do not have different price-efficiency parameters, k_1^i, i.e., they both succeed to the same degree in maximizing profits.

(iii) Equal Relative Technical *and* Price Efficiency

$$H_0: \delta_L^* = 0$$
$$\alpha_1^{*L} = \alpha_1^{*S}$$

This hypothesis is rejected. This actually can be anticipated in view of the rejection of hyphothesis (i).

(iv) Absolute Price Efficiency of Small Farms

$$H_0: \alpha_1^{*S} = \alpha_1^{*}$$

Maintaining the hypothesis of equal price efficiency in (ii), we test for absolute price efficiency of small farms. This hypothesis is not rejected at the 10 percent level, implying that the small farms have maximized profits, i.e., $k_1^S = 1$.

(v) Absolute Price Efficiency of Large Farms

$$H_0: \alpha_1^{*L} = \alpha_1^{*}$$

Also maintaining the hypothesis of equal relative price efficiency of (ii) we test for the absolute price efficiency of large farms. This hypothesis also cannot be rejected at the 10 percent level. This means that large farms have also maximized profits, i.e., $k_1^L = 1$. One could have expected this finding from the results of (ii) and (iv).

(vi) Constant Returns to Scale

$$H_0: \beta_1^* + \beta_2^* = 1$$

Maintaining the hypotheses (iv) and (v) we test for constant returns to scale to all factors of production. Again, this hypothesis cannot be rejected.[13]

Once a hypothesis is not rejected, we proceed to obtain estimates of parameters incorporating the hypothesis. The estimation results are tabulated in Table 2. As predicted by economic theory, the profit function is decreasing and convex in wage rate, and increasing in land. The wrong sign of the coefficient of capital can be attributed to a misspecification of this variable. Defining capital as interest charges on fixed assets per farm involves the implicit assumption that the service flow of capital, which is the appropriate input in production analysis, is proportional to the capital stock. As shown

[13] At this point compare the discussion of A. M. Khusro.

elsewhere (Yotopoulos (1967a, b)), this measure of capital leads to biased coefficients.

From our estimated parameters, we can compute, by (9) and (11), indirect estimates of the production elasticities of labor, capital and land as well as those of the technical-efficiency and price-efficiency parameters of the large and small farms. These are tabulated in Table 3. We note that the production elasticities thus estimated appear generally large by comparison with estimates of directly fitted Cobb-Douglas agricultural production functions reported in other studies. The obvious reason for this discrepancy

	k_1^L	0.903	1.000	1.000
Small Farms	A^S	18.658	14.639	17.723
	k_1^S	0.903	1.000	1.000

Note: For definition of variables, see Table 2.

[a] The indirect estimates of the coefficients of the production function are computed from the identities in (9). The efficiency parameters are computed from (9) and (11).

is the constraint of constant returns to scale combined with the negative coefficient of capital.[14] Conceptually, however, the indirect estimates of production coefficients are statistically consistent, as opposed to those obtained directly from the production function by ordinary least squares, which are in general inconsistent because of the existence of simultaneous equations bias. By examining the technical efficiency component for small and large farms in Table 3 we find that the former are approximately 20 percent more efficient than the latter.

IV. Summary and Conclusions

An operational model to measure separately relative technical efficiency and price efficiency between (groups of) firms has been developed and applied to Indian agriculture. Needless to say, the usefulness of the approach here is not restricted to agriculture; neither is it specific for comparing large and small farms.

The conclusion of the test of relative economic efficiency is in favor of the small farms, i.e., farms of less than ten acres, in agreement with our previous result in our 1971 article. Given the fixed inputs (land and fixed capital), and within the ranges of the observed prices of output and variable inputs (labor), the small farms of the sample of *The Studies* have higher actual profits. The relative economic efficiency of the small farms, however, is not due to superior price efficiency. In fact, we have found that both large and small farms are price-efficient.[15] It may, after all, be true that the marginal calculations which the market place requires of the farmer are relatively easy to make. More importantly, we have established the superior technical efficiency of the small farms.[16] We have also found that there exist constant returns to scale in Indian agriculture. Hence one cannot argue for a consolidation of small farms on the grounds of economies of scale.

These findings imply that in agriculture the direct supervisory and leadership role of

[14] The negative coefficient of capital has also appeared in other application with the same data. See Lau and Yotopoulos (1971) and Yotopoulos, Lau, and K. Somel.

[15] This finding is inconsistent with Amartya Sen's (1964, 1966) hypothesis that large farms maximize profits while small farms maximize utility.

[16] One possible explanation that has been advanced is an inverse proportional relationship between farm size and intrinsic fertility.

the owner-manager may be crucial for attaining high levels of economic efficiency. More studies are needed to further explain the so-called "unmeasureable factors" which apparently cause the difference in technical efficiency.

Welfare-Maximizing Price and Output with Stochastic Demand: Comment

By Michael L. Visscher*

In their model of a public utility firm which faces constant returns to scale and stochastic demand, Gardner Brown, Jr. and M. Bruce Johnson argued that "... the optimal price will always be lower and, with linear demand, the optimal output will generally be higher than their counterparts in the riskless model of traditional theory, regardless of the manner in which the disturbance term enters the analysis" (p. 119). Although their formal analysis is faultless, they are in error in attributing primary responsibility for their conclusions to the random element in the demand schedule. Their results can be shown to depend instead on their assumption of an unrealistic rationing system; when quantity demanded at the predetermined price exceeds capacity, they assume that available output will be allocated to those with the highest demand prices. Hence, the Brown and Johnson (B-J) approach assumes away the unique role of a market-clearing price in achieving an efficient rationing of the available product. It is the purpose of this note to show that if alternative assumptions are made concerning the way in which output is allocated when excess demand exists, different conclusions are reached about the nature of welfare-maximizing price and investment rules when demand is stochastic.

I. The Brown and Johnson Model

In one of the B-J models, a random disturbance term enters the demand function additively: $D=X(P)+u$, where D is actual quantity demanded, P is price, and u is a random variable which is distributed symmetrically about zero with continuous probability density function $f(u)$ and cumulative probability function $F(u)$. The public utility firm has the long-run cost function $C(Q)=(b+\beta)Q$, where Q is quantity produced, b is marginal operating cost, β is marginal capacity cost, and both b and β are constant. Before the actual value of u is known, the firm must choose a price $\overline{P}$ and a capacity Z to maximize a welfare function equal to expected consumers' surplus: $W=E$(willingness to pay) $-E$(average variable cost·sales) $-E$(capacity cost).

In order for the B-J model to be appropriate, the producer must be able to distinguish costlessly between claimants (i.e., all those willing to pay $\overline{P}$) and serve only those with the highest willingness to pay. Assuming this rationing procedure is possible, differentiating W with respect to the two choice variables, $\overline{P}$ and Z, yields marginal conditions

$$(1)\quad \frac{\partial W}{\partial \overline{P}} = \overline{P}X'(\overline{P})F[Z-X(\overline{P})] - bX'(\overline{P})F[Z-X(\overline{P})]=0$$

$$(2)\quad \frac{\partial W}{\partial Z} = \int_{Z-X(P)}^{\infty} f(u)\cdot[X^{-1}(Z-u)-b]du-\beta=0$$

From these conditions, Brown and Johnson conclude that the optimal price is b and that optimal capacity is greater than $X(b+\beta)$, the optimal capacity in a model of riskless deterministic demand.[1]

The B-J conclusion must, however, be qualified because (a) the optimal values of price and capacity depend critically upon which claimants are actually served, and (b) in the absence of a market-clearing price, the B-J rationing procedure simply is unavailable to the producer. When other assumptions are made about who is served, different solutions follow. Two alternative rationing procedures will be discussed.

* Graduate student, University of Virginia. This paper has benefited significantly from the comments of Roger Sherman and an anonymous referee. Remaining errors are my own.

[1] See Oliver Williamson, p. 812, for development of the riskless model.

II. Serving First Those with the Lowest Willingness to Pay

The B-J assumption can be depicted graphically in Figure 1. When a value of the error term, u is sufficiently high to result in excess demand at the previously chosen values of $\bar{P}$ and Z, available output is sold only to those claimants with the highest willingness to pay. Then the sum of consumers' surplus and total revenue is represented by the area $ABZO$ in Figure 1.

Suppose instead that service is offered first to those claimants with the least willingness to pay. Such an assumption may be relevant if, for instance, distribution is on a first-come, first-served basis, and those with the lowest opportunity costs on their time (and therefore most willing to pay by waiting) are also those with the lowest demand prices. Then the sum of consumers' surplus and total revenue in times of excess demand could be depicted as area $BCDE$ in Figure 2.

Analysis of this model can proceed in a manner similar to that of Brown and Johnson. The objective function will remain: $W = E$(willingness to pay) $- E$(average variable costs·sales) $- E$(capacity cost). If demand always could be satisfied, E(willingness to pay) would be the expected value of all possible values of consumers' surplus plus total revenue at the price chosen. But

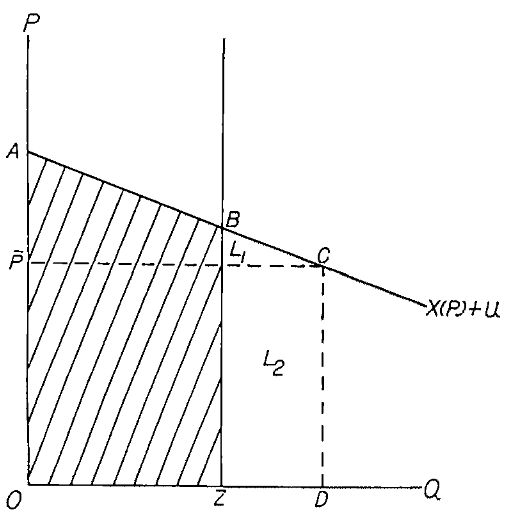

FIGURE 1

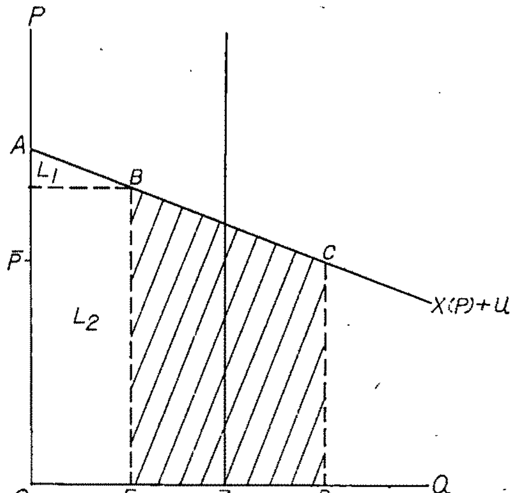

FIGURE 2

at some values of u, the demand cannot be satisfied. Such a value of u is depicted by the position of the demand function in Figures 1 and 2. If this high value of u manifests itself and those with the lowest willingness to pay are served first, (L_1+L_2) in Figure 2 must be subtracted from area $ACDO$ to arrive at total willingness to pay. The expected value of (L_1+L_2) in Figure 2 is:

$$(3) \quad E(L_1 + L_2) = \int_{Z-X(P)}^{\infty} f(u) \cdot \left\{ \int_{X^{-1}(-u)-X^{-1}(Z-u)+P}^{X^{-1}(-u)} [X(P) + u]dP + [X^{-1}(-u) - X^{-1}(Z-u) + \bar{P}] \cdot [X(\bar{P}) + u - Z] \right\} du$$

On subtracting this expected value, the welfare function becomes that shown in equation (4). (See following page.)

To maximize this objective function, we differentiate with respect to the two choice variables and set each differentiation equal to zero as shown in equations (5) and (6). Adding these two equations yields $\bar{P} = b + \beta$. Thus, in a model in which available output is rationed to those claimants with the smallest demand prices, optimal price is equal to

$$
(4) \quad \begin{aligned}
W = &\int_{-\infty}^{\infty} f(u) \int_{P}^{X^{-1}(-u)} [X(P) + u] dP du + \overline{P}X(\overline{P}) - \int_{Z-X(P)}^{\infty} f(u) \\
&\cdot \int_{X^{-1}(-u)-X^{-1}(Z-u)+P}^{X^{-1}(-u)} [X(P) + u] dP du \\
&- \int_{Z-X(P)}^{\infty} f(u)[X^{-1}(-u) - X^{-1}(Z-u) + \overline{P}][X(\overline{P}) + u - Z] du \\
&- b\left\{X(\overline{P}) - \int_{Z-X(P)}^{\infty} uf(u)du + [Z - X(\overline{P})] \int_{Z-X(P)}^{\infty} f(u)du\right\} - \beta Z
\end{aligned}
$$

$$
(5) \quad \frac{\partial W}{\partial P} = (\overline{P} - b)F[Z - X(\overline{P})] - \int_{Z-X(P)}^{\infty} f(u)[X^{-1}(-u) - X^{-1}(Z-u)]du = 0
$$

$$
(6) \quad \frac{\partial W}{\partial Z} = (\overline{P} - b)\left\{1 - F[Z - X(\overline{P})]\right\} + \int_{Z-X(P)}^{\infty} f(u)[X^{-1}(-u) - X^{-1}(Z-u)]du - \beta = 0
$$

$$
(7) \quad \left.\frac{\partial W}{\partial Z}\right|_{\substack{P=b+\beta \\ Z=X(b+\beta)}} = \int_{0}^{\infty} f(u)[X^{-1}(-u)]du - \int_{0}^{\infty} f(u)\left\{X^{-1}[X(b+\beta) - u]\right\} du - \frac{\beta}{2}
$$

long-run marginal cost just as in traditional riskless theory, and not short-run marginal cost as required under the rationing assumption made by Brown and Johnson.

Optimal capacity choice in the Figure 2 model is likewise different from that in the B-J model. Smaller values of Z (smaller even than riskless Z) are possible.[2]

If, when evaluated at

$$\overline{P} = b + \beta$$

and

$$Z = X(b+\beta),$$

$\partial W/\partial Z$ is negative, then optimal capacity is less than $X(b+\beta)$, for then increments to capacity at that output decrease the objective function. Yet if Z can be less than $X(b+\beta)$, it can surely be less Brown and Johnson Z, for that could never be less than $X(b+\beta)$. From equation (7), we can assert that optimal capacities less than those of the riskless model are indeed feasible.[3]

[2] In general, Brown and Johnson's conjecture, p. 123, fn. 8, on this point does not appear to hold.

[3] The same is true for a profit-maximizing monopolist under risk. See Edwin Mills, p. 93.

$X^{-1}(-u)$ is the price intercept of the observed demand function, and $X^{-1}(X(b+\beta)-u)$ is the price that would just clear the market for the observed value of u (Figure 3). Therefore, if demand is linear,

$$\left.\frac{\partial W}{\partial Z}\right|_{\substack{P=b+\beta \\ Z=X(b+\beta)}}$$

tends to decrease, *ceteris paribus*, if:

a) the demand function becomes more elastic at $P = b+\beta$ (for then the sum of the first two terms in (7) is less),

b) the short-run marginal cost, b, increases (for then the second term in (7) is less), or

c) the marginal capacity cost, β, increases (for then the last term in (7) is less). It is conceivable that any of these events might be sufficient to make optimal Z less than $X(b+\beta)$.

These solutions for $\overline{P}$ and Z can be squared with intuition. The penalty for

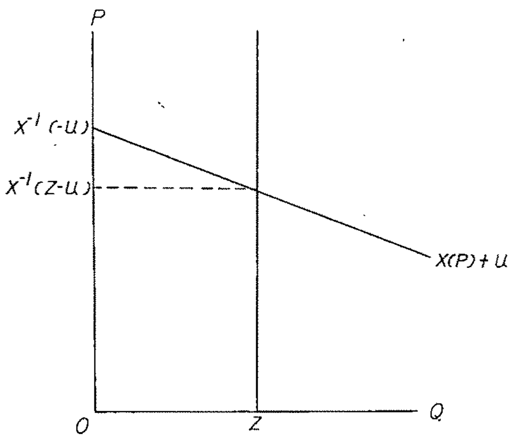

FIGURE 3

excess demand is that those with the highest willingness to pay will be denied service. To avoid this penalty, excess demand could be made less frequent by increasing both price and capacity. But at any given price, additions to capacity will be used to satisfy those who value the good relatively little. So, if the linear demand curve is sufficiently elastic at the higher price, or if either b or β are sufficiently high, then those that would benefit from additional capacity do not value the good enough to warrant the outlays extra capacity would entail. Output should then be restricted. Excess demand is made more frequent, but consumer surplus is conserved; those who are turned away value the service little relative to the cost of production.

III. Random Rationing of Available Capacity

Perhaps a more tenable assumption than either Brown and Johnson's or "least-valued served-first" is that order of service and willingness to pay are completely uncorrelated. If $X(\overline{P})+u$ units are demanded at $\overline{P}$ and only $Z<X(\overline{P})+u$ are available, let those Z units be distributed randomly among those claimants willing to pay $\overline{P}$. The expected value of the willingness to pay in periods of excess demand would then be $Z/[X(\overline{P})+u]$ of that which would be realized if the entire quantity-demanded could be met at the price $\overline{P}$. Therefore, we can calculate E(willingness to pay) by subtracting $E(L_1+L_2)$ from the expected value of area $AEDO$ (Figure 4) for those values of u large enough to cause excess demand at the $\overline{P}$ and Z chosen. Since $E(L_1+L_2)$ is given in equation (8), our objective function is equation (9). Maximizing the objective function with respect to $\overline{P}$ and Z, we obtain equations (10) and (11). The third term on the right-hand side of equation (11) is the expected value of area $AE\overline{P}$ divided by length $\overline{P}E$ (Figure 4) for all ($\overline{P}$, Z, u) combinations where excess demand occurs. The fourth term on the right-hand side is the expected value of area $AB\overline{P}$ divided by length $\overline{P}E$ for ($\overline{P}$, Z, u) combinations where excess demand occurs. This term must be less than the third term because realized consumers' surplus in times of excess demand is always less than that had all demand been met. Thus, we have $b<\overline{P}<b+\beta$.

Here, too, optimal Z can be less than that which was optimal in the B–J and riskless models. Let $\overline{P}=b+\alpha\beta$, where $0<\alpha<1$, and $Z=X(b+\beta)$ in $\partial W/\partial Z$. If $\partial W/\partial Z$ evaluated at that $\overline{P}$ and Z can be less than zero, optimal capacity can lie below $X(b+\beta)$, the riskless optimal capacity. See equation (12), page 228.

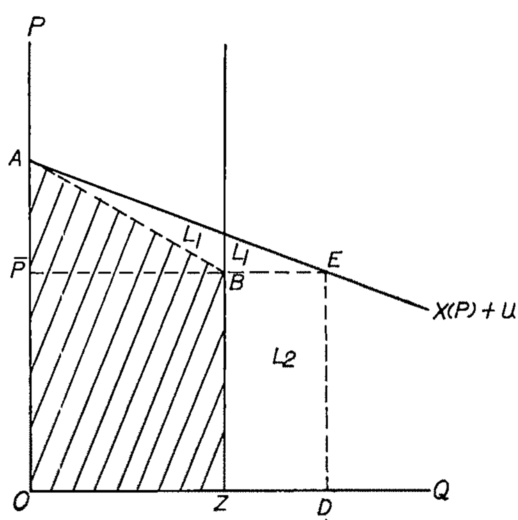

FIGURE 4

$$E(L_1 + L_2) = \int_{Z-X(P)}^{\infty} f(u)\left[1 - \left(\frac{Z}{X(\overline{P}) + u}\right)\right]\int_{P}^{X^{-1}(-u)} [X(P) + u]dPdu \tag{8}$$

$$+ \int_{Z-X(P)}^{\infty} f(u)[\overline{P}][X(\overline{P}) + u - Z]du$$

$$W = \int_{-\infty}^{\infty} f(u)\int_{P}^{X^{-1}(-u)} [X(P) + u]dPdu + \overline{P}X(\overline{P}) - \int_{Z-X(P)}^{\infty} f(u) \tag{9}$$

$$\cdot\left[1 - \left(\frac{Z}{X(\overline{P}) + u}\right)\right]\int_{P}^{X^{-1}(-u)} [X(P) + u]dPdu$$

$$- \int_{Z-X(P)}^{\infty} f(u)[\overline{P}][X(\overline{P}) + u - Z]du - bX(\overline{P}) + b$$

$$\cdot \int_{Z-X(P)}^{\infty} uf(u)du - b[Z - X(\overline{P})]\int_{Z-X(P)}^{\infty} f(u)du - \beta Z$$

$$\overline{P} = b + \frac{1}{F[Z - X(\overline{P})]}\int_{Z-X(P)}^{\infty} \frac{Zf(u)}{[X(\overline{P}) + u]^2}\int_{P}^{X^{-1}(-u)} [X(P) + u]dPdu > b \tag{10}$$

$$\overline{P} = b + \beta - \int_{Z-X(P)}^{\infty} \frac{f(u)}{[X(\overline{P}) + u]}\int_{P}^{X^{-1}(-u)} [X(P) + u]dPdu \tag{11}$$

$$+ \int_{Z-X(P)}^{\infty} \frac{Zf(u)}{[X(\overline{P}) + u]^2}\int_{P}^{X^{-1}(-u)} [X(P) + u]dPdu < b + \beta$$

$$\left.\frac{\partial W}{\partial Z}\right|_{\substack{P=b+\alpha\beta \\ Z=X(b+\beta)}} = \alpha\beta\int_{X(b+\beta)-X(b+\alpha\beta)}^{\infty} f(u)du - \beta + \int_{X(b+\beta)-X(b+\alpha\beta)}^{\infty} \frac{f(u)}{[X(b + \alpha\beta) + u]} \tag{12}$$

$$\cdot \int_{b+\alpha\beta}^{X^{-1}(-u)} [X(P) + u]dPdu$$

$$\left.\frac{\partial W}{\partial Z}\right|_{\substack{P=b+\alpha\beta \\ Z=X(b+\beta)}} = \alpha\beta\int_{X(b+\beta)-X(b+\alpha\beta)}^{\infty} f(u)du - \beta + \frac{1}{2}\int_{X(b+\beta)-X(b+\alpha\beta)}^{\infty} f(u)[X^{-1}(-u) - (b + \alpha\beta)]du \tag{13}$$

$$= \frac{1}{2}\left\{\int_{X(b+\beta)-X(b+\alpha\beta)}^{\infty} f(u)[X^{-1}(-u)]du\right.$$

$$\left. + (\alpha\beta - b)\int_{X(b+\beta)-X(b+\alpha\beta)}^{\infty} f(u)du - 2\beta\right\}$$

If $X(P)$ is linear (as Brown and Johnson also assume), then $\partial W/\partial Z$ is given by equation (13), page 228. The value of $\partial W/\partial Z$ may be less than zero, as in the case of the "least-valued served-first" model, and is more likely to be negative the more elastic is the demand function at $\bar{P}$, the larger is β, and the larger is b, *ceteris paribus.*

IV. Conclusion

Were all transactions costless, we would not need to concern ourselves for the sake of efficiency with the manner in which the producer allocates service among potential claimants when excess demand exists. An implicit market-clearing price is then established regardless of the price set by the producer because of the possibility of trades among claimants. For instance, if the producer chose the B–J price of b, those consumers with the highest demand prices would bid away service from those with the lowest demand prices by offering appropriate side payments. The result would be efficient (in the static sense) since only those with the highest willingness to pay would be served. But such transactions are prohibitively costly, so when demand is uncertain and more service may be demanded than can be supplied at the announced price, the optimal values of price and capacity will depend on how available capacity is initially rationed.

The relation between the rationing assumption which governs who is served and the optimal values of price and capacity can be summarized in the following table:

Model	Price	Capacity
Riskless (Deterministic) Demand	$b+\beta$	$X(b+\beta)$
Highest Demand Prices Served First (B-J)	b	$>X(b+\beta)$
Lowest Demand Prices Served First	$b+\beta$	$X(b+\beta)$ depending on cost and demand parameters
Capacity Distributed Randomly Among All Willing to Buy at $\bar{P}$	$b+\alpha\beta$ $0<\alpha<1$	$X(b+\beta)$ depending on cost and demand parameters

For the B–J results to hold, the producer must insure that only those with the highest willingness to pay are served. But, except by price, no feasible means of distinguishing among claimants exists. Consequently, optimal capacity will be different from that defined by Brown and Johnson, and optimal price will be nearer to that of the riskless model.

Welfare-Maximizing Price and Output with Stochastic Demand: Reply

By Gardner Brown, Jr. and M. Bruce Johnson*

We concluded in our 1969 article that when a public monopoly must choose both price and capacity output before it knows the position of the stochastic demand curve, optimal price should equal short-run marginal cost and optimal capacity output should, in general, exceed riskless capacity output. Michael Visscher claims our results depend on an unrealistic rationing system. He proposes two alternative rationing schemes: distribution of the product to those customers with the lowest (rather than the highest) willingness to pay, or distribution to customers on a random basis without regard for willingness to pay. His intuition is correct; different assumptions lead to different conclusions.

Our analysis supressed the costs of identifying those customers with the highest willingness to pay. Visscher challenges this assumption but de facto adopts it himself when he supposes that the product is offered to those claimants with the least willingness to pay. He asserts that if distribution is on a first-come, first-served basis and if consumers "with the lowest opportunity costs on their time (and therefore most willing to pay by waiting) are also those with the lowest demand prices," his rationing scheme is relevant. The second assertion is gratuitous.

There are neither theoretical nor empirical grounds to support the view that willingness to pay is correlated with opportunity cost; even if one were willing to assume that the value of time is equal to the wage rate, the result would not follow. Moreover, in some cases the decision to consume the product requires commitment of a block of time to the activity before one knows whether or not there will be excess demand. For example, the decision to camp in a public park involves a trip to the park site. Once at the site the decision to enter a queue (if one exists) depends on one's subjective disutility of queuing, not on the money wage rate one would have earned if one had remained at his job site. Consequently, if one is at the entrance to the park, the opportunity cost of one's time in productive activities probably is zero. By implication, one cannot conclude that those customers with the lowest opportunity cost are most likely to stand in line for the product.

In any event, neither our model nor the neoclassical excludes the possibility that those potential consumers with the highest willingness to pay will hire other consumers with low opportunity cost to stand in line for them. More formally, a reservation or a right to use the product may be transferred among customers. The initial distribution of rights is irrelevant since free trade among the participants will redistribute the product to those customers with the highest willingness to pay. Visscher's first model would be relevant as stated only if resale and transfer of rights were prohibited by law or if high customer search and transfer costs existed.

According to our model, optimum price equals short-run marginal cost b. Given that long-run marginal (and average cost) is $b+\beta$, the public monopoly will incur a loss. However, the public authority can recover its fixed cost by selling rights to use the Z^* units of capacity at a price of β each in a futures market. The operation will "break even" since $(b+\beta)\ Z^*$ equals both receipts and expenditures. Speculators will purchase rights at the price of β as long as the market includes one risk neutral trader or, in the vernacular of J. M. Keynes, pp. 142–44, if the futures market does not exhibit normal

* Departments of economics, University of Washington and University of California, Santa Barbara, respectively.

backwardation, i.e., if speculators do not demand a risk premium.[1]

On the average, those customers who desire a product would be willing to pay:

$$\int_{Z-X(p)}^{\infty} f(u)[X^{-1}(Z-u)-b]du=\beta$$

in the futures market and b per unit at the time of delivery. On the average speculators as a group will receive β per unit. This futures market performs its classical function: public authorities are able to hedge against risk and those individuals with a flair for risk management have the opportunity to exercise their talents. Our explicit introduction of a futures market in the section titled "The Way Back," shifted a portion of consumers' surplus (a rectangle whose dimensions are β and Z^*) from the consumers to the producer. Since the producer and consumer components have equal weight in our welfare function, our measure of welfare is unchanged by the introduction of futures markets. Furthermore, our welfare index will display a higher value than the index implicit in Visscher's solution where the product is distributed randomly, or to those individuals with the lowest willingness to pay.

On balance, Visscher's contribution is a constructive one. Transactions and recontracting costs have been troublesome in neoclassical static price theory for some time. However, it is easier to note their existence and speculate on their importance than it is to specify the exact details of a "real time" distribution scheme in a systematic and rigorous way. That task remains to be done both in our model and in the neoclassical competitive model.

[1] Years ago some futures markets for inactively traded commodities did display normal backwardation (see Roger Gray), but contemporary evidence suggests that speculators in 25 of the major commodity futures markets are risk neutral (see Charles Rockwell, pp. 107, 109). The profession remains divided on this issue (see Paul Cootner).

Erratum

The conclusion of Section I-A, page 124 of our 1969 article is correct: $Z^*>\bar{Z}$. However, the argument is imperfect due to the omission of the coefficient β from equation (17). Add β to the left-hand side of (17) and rearrange to give:[2]

$$\delta=-\frac{1}{B}\left[B\beta\int_{-\infty}^{B\beta} f(u)du+\int_{B\beta}^{\infty} uf(u)du\right] \tag{17'}$$

But

$$\int_{B\beta}^{\infty} uf(u)du=-\int_{-\infty}^{B\beta} uf(u)du \quad \text{since } E[u]=0$$

Thus,

$$\delta=-\frac{1}{B}\int_{-\infty}^{B\beta} f(u)[B\beta-u]du \quad \text{after substitution}$$

The limits on the integral are such, that $-\infty<u\leq B\beta$ where $B<0$ and $\beta>0$ by construction. $u\leq B\beta$ implies $[B\beta-u]\geq 0$. Hence the integral is positive and $\delta>0$.

Dependency Rates and Savings Rates: Further Comment

By ARTHUR S. GOLDBERGER*

The empirical results on dependency rates and savings rates reported by Nathaniel Leff (1969) cannot be correct.

For several cross-country samples, Leff estimates pairs of equations of the form

$$(1)\quad y_1 = a_0 + a_1x_1 + a_2x_2 + a_3x_3 + a_4x_4 + e_1$$

$$(2)\quad y_2 = b_0 + b_1x_1 + b_2x_2 + b_3x_3 + b_4x_4 + e_2$$

where

$y_1 = ln\ S/Y = ln$ domestic savings ratio
$y_2 = ln\ S/N = ln$ per capita savings
$x_1 = ln\ Y/N = ln$ per capita income
$x_2 = g =$ growth rate of per capita income
$x_3 = ln\ D_1 = ln$ percentage of population aged 14 or less
$x_4 = ln\ D_2 = ln$ percentage of population aged 65 or more,

and a and b are least-squares regression coefficients, and e_1 and e_2 are least-squares residuals.

As noted by Leff, $S/N \equiv (S/Y)(Y/N)$. Consequently, $y_2 = y_1 + x_1$. Least-squares regression being what it is, a proper computation of (2) should produce

$$(3)\quad y_2 = a_0 + (1 + a_1)x_1 + a_2x_2 + a_3x_3 + a_4x_4 + e_1$$

That is, regressing y_2 on the x should give the same coefficients and the same residuals as occur when y_1 is regressed on the x, except for the coefficient of x_1, which should increase by exactly 1.

Furthermore, if regression coefficients are guaranteed to be equal, their standard errors, and hence their t-ratios, must be equal. If regression coefficients are guaranteed to differ by unity, their standard errors must be equal, and hence their t-ratios must be related by

$$b_1/s_{b_1} = (a_1/s_{a_1})((1 + a_1)/a_1)$$

But the results Leff reports do not satisfy these arithmetic requirements. For example, consider the upper panel of his Table 1, p. 891, which refers to a sample of 47 underdeveloped countries. In the present notation we find:

Explanatory variable $j=$	1	2	3	4
Coefficients:				
a_j	.1292	.0227	−1.2297	−.4455
b_j	1.1167	.0239	−1.3122	−.4469
t-ratios:				
a_j/s_{a_j}	1.8487	2.8079	2.7636	2.1554
b_j/s_{b_j}	16.8355	3.1204	2.9400	2.2783

Something must be wrong.

For the same reasons, the empirical results reported by Kanhaya Gupta cannot be correct. Gupta fits (1) and (2) to 3 subgroups of Leff's sample, using Leff's data. His results also fail to satisfy the arithmetic requirements noted above. For example, consider the first panel of his Table 2, p. 470, which refers to 9 underdeveloped countries. In the present notation we find:

Explanatory variable $j=$	1	2	3	4
Coefficients:				
a_j	.4548	.1263	−.7685	−.6475
b_j	1.6112	.1309	−1.0487	−.5585
t-ratios:				
a_j/s_{a_j}	.3768	.3737	.1481	.9446
b_j/s_{b_j}	1.6008	.4644	.2424	.9770

The discrepancies are somewhat more striking in this subsample.

Perhaps none of the discrepancies noted here is large enough to vitiate the substantive analyses of Leff and Gupta. But it is disturbing that figures, some of which are

* Professor of economics, University of Wisconsin, Madison.

transparently wrong in the first decimal place, are reported to four decimal places.

One's first reaction is to attribute such discrepancies to computational inaccuracies. (Indeed, G. M. Mullet and T. W. Murray recently proposed fitting equation pairs like (1)–(2) to check the accuracy of computer programs.) But in the present case, the explanation lies elsewhere. The basic data constructed by Leff, and used by him and Gupta, were internally inconsistent. Scanning the series, which were kindly provided to me by Leff, one finds that, country by country, there are substantial discrepancies between per capita savings and the product of the savings ratio times per capita income. For example, for the first two countries in the list, we find

S/N	S/Y	Y/N	$(S/Y)(Y/N)$
43.7	.101	585	59.1
20.6	.094	271	25.5

Since $y_2 \neq y_1 + x_1$, the argument which led us to (3) loses its force. But it's difficult to see how an economic analysis of the relationship between savings rates and dependency rates can be based on data which are so internally inconsistent.

Dependency Rates and Savings Rates: Reply

By NATHANIEL H. LEFF*

Arthur Goldberger's comment is a tempest in a teacup. This is readily verified from the data presented in Table 1. This table reproduces from my original paper the coefficients for paired equations estimated with three different samples in which $ln\ S/N$ and $ln\ S/Y$ were the dependent variables.

As the data of Table 1 indicate, in 7 of the 12 cases, the coefficients are identical through the second decimal place. Furthermore, all the discrepancies are quantitatively very small. In 9 cases, the paired parameter estimates are within 1 percent of each other. In the remaining cases, the differences are of the magnitude of .0825, .0012, and .0011. These are well within the margins of accuracy within which anyone views data generated from the national income accounts of the less developed countries. In light of these considerations, it is difficult to understand the tone of Goldberger's comment.

The reason for the slight discrepancies is straightforward. My observations for S/N and S/Y were computed separately from data supplied by the Statistical Office of the Agency for International Development. With the rounding introduced by the series for N and Y, it is not surprising that the series for S/N is not identically equal to the series which would be obtained by forming S/N from the product of Y/N and S/Y. Similar slight discrepancies have also been reported in other econometric work in which equations for S/N and S/Y have been estimated with separately computed data series.[1]

In any case, nowhere in my paper did I even refer to the precise numerical parameter estimates obtained in my equations. The main conclusions of the paper were that the dependency variables were quantitatively an important determinant of international savings rates, and, further, that introduction of these variables greatly reduced the importance of percapita income, on which some previous discussions had focused. Neither of these conclusions is affected by Goldberger's comment.

Source: Data presented on pp. 889–891 of my 1969 article.
Note: The constants of equations (1) and (2) differ by approximately 4.6 (equal the antilog of 100). This shift by a factor of 100 occurs because, as stated on p. 888 of my paper, S/Y is expressed in percentage *points.*
Equation (1): $ln\ S/Y = a_0 + a_1\ ln\ Y/N + a_2\ ln\ g + a_3\ ln\ D_1 + a_4\ ln\ D_2$
Equation (2): $ln\ S/N = b_0 + b_1\ ln\ Y/N + b_2\ ln\ g + b_3\ ln\ D_1 + b_4\ ln\ D_2$

Behavior of the Firm Under Regulatory Constraint: Clarifications

By MOHAMED EL-HODIRI AND AKIRA TAKAYAMA*

In the note by Israel Pressman and Arthur Carol (P-C) relating to Takayama's paper (T) on the Averch-Johnson effect (A-J), it seems useful to clarify the following points.

I. The Shift of the Curve

The major point of criticism on A-J by T, is that (A-J) "... involves an error of confirming the movements along the curve with the shift of the curve" (T, p. 257). This point seems to be obvious from Figure 1 in T, p. 258, but it looks like P-C has a serious objection to this (see p. 211). Mathematically the point of T is even simpler. Consider a continuous real-valued function defined on the nonnegative orthant of R^2, $f(x_1, x_2)$. Suppose one of the variables (say x_1) is fixed as a, and ϕ is defined by

$$\phi(x_2) = f(a, x_2)$$

The value of ϕ can be plotted against x_2. Then the marginal-revenue-product-of-capital curve ($MRPK$) in Figure 1 of T is a curve, where x_1 and x_2 are identified as labor and capital, respectively, and f is identified as the marginal revenue product of capital. Obviously the value of f would change when the value of x_1 changes from a to some other value, *even if the value of x_2 remains the same.* This is the "shift" of the ϕ curve, and the shift of the G_k curve in T. Such a shift of the ϕ curve will *not violate the continuity of the f function*, contrary to P-C's objection to T.

The "Averch-Johnson effect" says in essence that a firm tends to increase its investment. In order to conclude that the value of $f(x_1, x_2)$ increases, it is not sufficient to say that f is a decreasing function in x_2 for each fixed value of x_1 (see Figure 1 of T, p. 258). In T, the proof of the A-J effect is spelled out in detail in Section II, pp. 259–260. It is a usual comparative statics procedure which is familiar to economists. Somehow P-C fail to appreciate the significance of this proof as compared to the original A-J argument used to show the A-J effect. (See, for example, P-C's Figure 1, p. 212.)

II. Proof of the A-J Effect

P-C claim that the A-J effect in both T and A-J could be proved only if it is assumed to start with that the Lagrangian multiplier λ^* is strictly between zero and one. Their contention is based on the assertion that the continuity of $\lambda(s)$ at $s=0$ (where s is the upper bound on returns to capital) "... could not be proved ..." without at least one of the above assumptions. Rather than proving this impossibility, P-C claim that it is possible to prove that if the A-J effect holds or if $0<\lambda^*<1$, then the A-J effect holds. The difference should be obvious.

When $0<\lambda^*<1$, the proof of A-J effect is spelled out in Section II of T which P-C apparently ignore. In the following, we shall show that it is not necessary to assume that $0<\lambda^*<1$ nor the conclusion, in order to prove the A-J assertion.

We think that a part of their error may be caused by the notation. We shall denote the return on capital by ρ, so that:

$$\rho \equiv \frac{\pi + rK}{K}$$

where $\pi = \pi(L, K) \equiv pF(L, K) - wL - rK$, and denotes profit in T. We use superscript o to denote the unconstrained profit maximum and the asterisk to denote the constrained profit maximum. For the rest, we use the notation of T.

* Associate professor of economics, University of Kansas, and professor of economics, Purdue University, respectively. We are grateful to Professor Paul W. McAvoy for pointing out an error in an earlier draft.

Assume that

$$\pi(L, K)\big|_{L=K=0} = 0$$

and that $s>0$. Assume, following T and P-C, that $L^0>0$, $K^0>0$, $L^*>0$ and $K^*>0$.[1] Then we obtain that π^0, the unconstrained profit maximum, and π^*, the constrained profit maximum, are positive.[2] Following T, denote the marginal revenue product of labor ($MRPL$) and the marginal revenue product of capital ($MRPK$) by G_L and G_K, respectively. Write $G_L^* \equiv G_L(L^*, K^*)$, $G_K^* \equiv G_K(L^*, K^*)$, $G_L^0 \equiv G_L(L^0, K^0)$ and $G_K^0 \equiv G_K(L^0, K^0)$. Then the unconstrained case is characterized, in view of the concavity[3] of π, etc., by

$$\text{(1a)} \qquad G_L^0 = w$$

$$\text{(1b)} \qquad G_K^0 = r$$

The regulatory constraint is $\rho \leq s$. Hence:

$$\rho^* \leqq s \quad \text{where} \quad \rho^* \equiv \rho(L^*, K^*);$$

i.e.,

$$\pi^* + rK^* = \rho^* K^* \leqq sK^*,$$

and so

$$\pi^* \leqq (s-r)K^*$$

Since $\pi^*>0$ and $K^*>0$ we have:

$$\text{(2)} \qquad r < s$$

For the constrained case we have at (L^*, K^*):

$$\text{(3a)} \qquad (1-\lambda^*)G_L^* = (1-\lambda^*)w$$

$$\text{(3b)} \qquad (1-\lambda^*)G_K^* = r - \lambda^* s$$

$$\text{(3c)} \qquad \lambda^* \geqq 0 \quad \text{and}$$

$$0 = \lambda^*(sK^* + wL^* - G^*) \qquad (=\lambda^*(s-\rho^*))$$

[1] Needless to say, (L^0, K^0) denotes a solution for the unconstrained case and the (L^*, K^*) denotes a solution for the constrained case.

[2] Otherwise (L^0, K^0) and (L^*, K^*) are not solutions of the respective maximization problems, except for the trivial case. Needless to say, $L=K=0$ means "do nothing."

[3] For some discussion in which the usual first-order condition gives a necessary and sufficient characterization of optimum, see T.

Assuming that G is concave, we have:

$$\text{(4a)} \qquad G^0 - G^* \leqq G_L^* \cdot (L^0 - L^*) + G_K^* \cdot (K^0 - K^*)$$

$$\text{(4b)} \qquad G^* - G^0 \leqq G_L^0 \cdot (L^* - L^0) + G_K^0 \cdot (K^* - K^0)$$

$$\text{(4c)} \qquad G(0,0) - G^* \leqq G_L^* \cdot (0 - L^*) + G_K^* \cdot (0 - K^*)$$

where $G(0,0) = G(K, L)\big|_{K=0, L=0}$

Now $\lambda^* \neq 1$, since $\lambda^*=1$ implies, by (3b), that $r=s$ contradicting (2). Hence $(1-\lambda^*) \neq 0$, and by (3a) we have:

$$\text{(5a)} \qquad G_L^* = w$$

By (3b) we have

$$\text{(5b)} \qquad G_K^* - r = \lambda^* G_K^* - \lambda^* s$$

By (1) and (5a) we write (4a) and (4b) as:

$$\text{(6a)} \qquad G^0 - G^* \leqq w \cdot (L^0 - L^*) + G_K^* \cdot (K^0 - K^*)$$

$$\text{(6b)} \qquad G^* - G^0 \leqq w \cdot (L^* - L^0) + r \cdot (K^* - K^0)$$

By our assumption that $\pi(0,0)=0$, we have $G(0,0)=0$. We write (4c) as:

$$G^* \geqq G_L^* L^* + G_K^* K^*$$

Thus, by (5a), we have:

$$\text{(6c)} \qquad G^* \geqq wL^* + G_K^* K^*$$

Adding (6a) and (6b) we get:

$$\text{(7)} \qquad 0 \leqq (G_K^* - r)(K^0 - K^*)$$

By (7), $K^* \geqq K^0$ if, and only if, $G_K^* - r \leqq 0$.

We further, by (3c), have:

$$\lambda^* sK^* = \lambda^* G^* - \lambda^* wL^*$$

Thus, by (5b), $(G_K^* - r)K^* = \lambda^* G_K^* K^* + \lambda^* wL^* - \lambda^* G^*$. But, by (6c) and $\lambda^* \leqq 0$, $\lambda^* G_K^* K^* + \lambda^* wL^* - \lambda^* G^* \leqq 0$. Thus, since $K^*>0$, $G_K^* - r \leqq 0$. Hence, $K^* \geqq K^0$, which

is the "weak" A-J effect. If we assume $K^* \neq K^0$ then $K^* > K^0$ which is the "strong" A–J effect.

III. Relation to $0<\lambda^*<1$

The above argument shows that the A-J assertion could be proved *without assuming that* $0<\lambda^*<1$. To show that $\lambda^*>0$ we need only to assume that $K^0 \neq K^*$ and that (1) has a unique solution.[4] Indeed, if $\lambda^*=0$ then (3) becomes $G_L^*=w$ and $G_K^*=s$. It is true that $\lambda^*<1$ if, and only if, $G_K^* \leq r$, i.e., if, and only if, $K^* \geq K^0$ by (7). This is true since, by (2) and (3b):

$$(1-\lambda^*)G_K^* < (1-\lambda^*)s$$

Recalling that $\lambda^* \neq 1$, we have: $(1-\lambda^*)(G_K^*-s)<0$. Also, by (5b)

$$G_K^* - r = \lambda^*(G_K^* - s)$$

Thus P-C are "almost" correct in concluding that $0<\lambda^*<1$ if, and only if, $K^*>K^0$. But they are wrong in stating that the A-J effect is impossible to prove without assuming A-J effect or $0<\lambda^*<1$.[5] In other words, one can prove that $\lambda^*>0$ without assuming the A-J effect and one can prove the A-J effect without assuming anything about λ^*.

[4] From an elementary knowledge of the non-linear programming theory with inequality constraints λ^* as defined in T is restricted as $\lambda^* \geqq 0$ (see condition f in T (p. 256)). This remark is probably necessary in view of equation (15) of P-C.

[5] See P-C's argument leading to their equation (17), p. 212. Incidentally, their argument (apparently using their Figure 1) falls into the error of confusing the shift of the curve and the movement along the curve, which T pointed out.

Behavior of the Firm Under Regulatory Constraint: Reply

By Israel Pressman and Arthur Carol*

We completely agree that it would be useful to clarify the papers by Harvey Averch and Leland Johnson, and by Akira Takayama. Rather than clarify, however, Mohamed El-Hodiri and Takayama (E-T) have tried to reinforce their arguments to prove an unproveable result and have resorted to the same assumptions and methods of the paper by Takayama.

It is apparent that E-T have confused a function of one variable with a function of two variables. Clearly if the value of a changes then it is not the value of f that changes, but the entire function $f(a, x_2)$ becomes a new function. Furthermore, E-T continue to misinterpret the "A-J effect" as "in essence that a firm tends to increase its investment." This is not the effect that A-J attempt to prove. A-J's statement of the overcapitalization effect is that "The firm will substitute capital for the other factor of production and operate at an output where cost is not minimized" (p. 1053). In other words, the optimum capital-to-labor ratio for the regulated firm will exceed the optimum capital-to-labor ratio for the unregulated firm. The result that $K^* > K^0$ is a foregone conclusion and is implied by the assumptions of the model and does not have to be proved.

It has been shown by L. Courville that a proof of overcapitalization requires the additional assumption of strictly convex isoquants. That this is so can be seen from the diagrams of E. E. Zajac, p. 120, that require the isoquants to intersect the constraint curve in two points. This is possible only if the isoquants are strictly convex. Thus, Courville has strengthened our contention "that the very assumptions used to prove the A-J Effect . . . require an assumption that the A-J Effect exists in the first place" (p. 210).[1]

With regard to T's comparative statics procedure, p. 259–260, it should be pointed out that comparative statics should be applied very carefully and only in the vicinity of the optimum. Incorrectly applied it leads to unsound conclusions. For example, equation (23) of T, p. 259, implies that

$$dk^*/k^* = ds/(r - r_0)$$

or that the change in capital is independent of the $MRPK$, a very unsound economic implication.

Finally, it should be pointed out that strict concavity of any function doesn't imply that the second derivative is negative everywhere. For example the function $f(X) = -X^4$ is strictly concave, but $f''(0) = 0$.

NOTES

A new organization, the History of Economics Society, has been organized for the purpose of stimulating interest and research in the history of economics, encouraging communication and interaction among scholars working in the field, and exposing members of the profession, particularly younger ones, to many facets of the broad scientific-literary-philosophic tradition of our discipline.

The members of the Executive Committee are William Allen, Robert Eagly, Craufurd Goodwin, William Grampp, William Jaffé, Warren Samuels, Joseph Spengler, George Stigler, and Vincent Tarascio. Anyone interested in participating as a member of the Society should communicate directly with Vincent J. Tarascio, Chairman, Executive Committee, History of Economics Society, Economics Department, University of North Carolina, Chapel Hill, North Carolina 27514.

Invest-in-America announces an essay contest open to members of economic faculties. The essay should identify current problems of the American economy, and the essayist should tell what he foresees as the major economic problems of the next ten years. Essays should not exceed three thousand words, double spaced typed, and should be submitted by Sept. 1, 1973. Send manuscripts to Invest-in-America National Council, Inc., Suite 906-907, 117 South 17th Street, Philadelphia, Pennsylvania 19103. Prizes of $250.00, $150.00, and $100.00 will be announced May 1, 1974.

New Journals

The *Industrial Organization Review* will begin publication with the spring issue in 1973. The *Review* will be published initially three times a year. It will be devoted to technical and empirical papers in the area of applied microeconomic theory, as well as studies of industry structure, conduct, and performance. It will also carry occasional papers which deal with policy questions of substantial significance. Manuscripts should be submitted to Managing Editor, *Industrial Organization Review*, Building 276, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061.

The *Journal of European Economic History* is an international scientific journal addressed to the community of scholars in economic history. It is published in the English language and appears three times a year. The editor is Luigi de Rosa, formerly professor of economic history at the University of Bari, and now at Naples. The American members of the editorial board are Shepard B. Clough and Ira Glazier with offices at Temple University. Contributions and suggestions for articles and book reviews are invited. The *Journal* is published by the Banco di Roma, Via del Corso, Rome. No charge is made for subscriptions to institutions and professional economic historians.

The *Home Economic Research Journal* is a new publication of the American Home Economics Association, a professional organization dedicated to the improvement of the quality and standards of individual and family life. The *Journal* provides a medium for reporting and recording the significant research that is being conducted today in home economics. All material will be refereed and must meet high standards, both in the research and in its presentation. Manuscripts may be submitted to the editor, Geitel Winakor, MacKay Hall, Iowa State University, Ames, Iowa 50010. A guide for authors may be obtained from the editor or from the American Home Economics Association, 2010 Massachusetts Ave., N.W., Washington, D.C. 20036.

A three-week Short Course for college teachers of economics will be held at Northern Illinois University from August 6–24, 1973. The workshop is supported by a grant from the National Science Foundation. The program will acquaint teachers of undergraduates with a wide range of computer-assisted instruction (CAI) techniques in economics. Thirty participants will be selected from junior and community colleges, four-year undergraduate institutions, and universities. For application forms and further information, write Professor John C. Soper, Department of Economics, Northern Illinois University, DeKalb, Illinois 60115.

A National Symposium on Ultimate Disposal of Wastewaters and Their Residuals will be held in Durham, North Carolina on April 26 and 27, 1973. Sponsored by the Research Triangle Universities and several national organizations, the program will include sessions on land disposal, marine disposal, sludge handling, design practice, recovery, and recycling. For further information, please contact F. E. McJunkin, Associate Director, Water Resources Research Institute of the University of North Carolina, North Carolina State University, 124 Riddick Building, Raleigh, North Carolina 27607.

The Committee on the Undergraduate Program in Mathematics (Mathematical Association of America) has recently published a report entitled *Introductory Statistics Without Calculus*. Intended as a guide for departments which offer a basic service course in statistics for students who have not studied calculus, this document contains recommended objectives for such a course and a discussion of their implications. A detailed outline is given for a conventional course in introductory statistics, while some alternate approaches (decision-theoretic, nonparametric, problem-oriented) are also discussed. The report considers the use of data sets, computers, experiments, and various teaching aids. It contains a selected bibliography of almost 100 titles. Copies of the report are available without charge from the CUPM Central Office, P.O. Box 1024, Berkeley, California 94701.

The University of Denver Graduate School of International Studies announces a conference on Comparative Public Policy: Process, Output, and Tradeoffs to be held November 21–23, 1973. Papers are being solicited and younger scholars are encouraged to make submissions. Papers must involve either cross-national or cross-issue comparisons. Preference will go to papers dealing with allocational decision making or analysis of output regarding defense and/or welfare. Authors whose papers are accepted for delivery will receive an honorarium of $300 and consideration for publication. For further information, write to William Loehr, Assistant Dean, Graduate School of International Studies, University of Denver, Denver, Colorado 80210.

The American Academy of Political and Social Science recently assembled a group of leading American social scientists who conferred for two days on the subject, "Integration of the Social Sciences through Policy Analysis." Three principal papers and nine written critiques were prepared and published in a monograph. Anyone wishing to have a copy of this monograph may obtain one free by writing to this Academy at 3937 Chestnut Street, Philadelphia, Pennsylvania 19104.

A complete set of *The American Economic Review* through 1950 is available as a donation to a small college or foreign institution. For information, write Professor Robert R. Dince, Department of Banking and Finance, Varsity, Building, University of Georgia, College of Business Administration, Athens, Georgia 30601.

The fourth Congress of the International Economic Association will be held in Budapest from 19 to 25 August 1974 on the general theme, *Economic Integration: Regional and Sectoral*. The program committee consists of Fritz Machlup, Chairman, Bela Balassa (*US*), Raymond Barre (France), O. T. Bogomolov (*USSR*), Bela Czikos-Nagy (Hungary), Robert Gardiner (Africa), Herbert Giersch (West Germany), Harry Johnson (*UK*), Ryitaro Komiya (Japan), Erik Lundberg (Sweden), Jozef Pajestka (Poland), and Raul Prebisch (Latin America). The program will include plenary sessions as well as meetings of ten separate working groups dealing with various aspects of the main theme. Details will be announced within the next few months. The address of the IEA Secretariat is 54 Boulevard Raspail, 75270 Paris Cedex 06 (Secretary General—Professor Luc Fauvel). Professor Mihaly Simai, Hungarian Economic Association, Kossuth Lajos Ter. 4, Budapest V, is in charge of local arrangements.

Fulbright-Hays Program for Senior American and Foreign Scholars in Economics and Business Administration

Applications will be accepted this spring for more than 550 lecturing and advanced research awards during 1974–75 in over 75 countries under the senior Fulbright-Hays program, the Committee on International Exchange of Persons announced recently. Specialists in economics who are U.S. citizens and have a doctorate or college teaching experience are invited to indicate their interest in an award by completing a simple registration form, available on request from Senior Fulbright-Hays Program, 2101 Constitution Avenue, Washington, D.C. 20418. Registrants will receive a detailed announcement of the 1974–75 program in May. The deadline for applying for research awards is July 1, 1973 and it is also the suggested date for filing for lectureships.

Applications from senior foreign scholars for temporary appointments at American colleges or universities are transmitted to the Committee each year by Fulbright-Hays agencies abroad. The scholars are eligible for a Fulbright-Hays travel grant upon receiving a lecturing or research appointment. An annual list of such scholars is issued in March. Also available is a list of 26 senior Fulbright-Hays foreign scholars in economics who are in the United States this academic year. A number of them would be pleased to accept invitations to give some lectures or to participate in special conferences under the sponsorship of academic institutions and educational organizations.

Deaths

Leland Louis Howell, Reno, Nevada, Nov. 20, 1972.

Retirements

George H. Hand, professor of economics, Southern Illinois University, Sept. 1, 1971.

Taylor D. MacLafferty, associate professor of business administration, Emory University, Sept. 1, 1972.

Vernon Morrison, professor of economics, Southern Illinois University, June, 1972.

Visiting Foreign Scholars

Do Yung Chung, Sung Kyun Kwan University: visiting professor of economics, Thunderbird Graduate School, fall 1972.

Nicos E. Devletoglou, London School of Economics and Political Science, University of London: Texas A&M University, spring 1973.

Promotions

Robert F. Allen: associate professor of economics, University of Nebraska, 1972–73.

Evan E. Anderson: associate professor, Graduate School of Business Administration, Tulane University, July 1, 1972.

A. Paul Ballantyne: professor, College of Letters, Arts, and Sciences, University of Colorado, June 1972.

Douglas Bohi: associate professor of economics, Southern Illinois University.

E. Gerald Corrigan: senior economist and assistant secretary, research and statistics function, Federal Reserve Bank of New York.

William P. Culbertson: assistant professor, department of economics, University of Virginia, Feb. 1. 1972.

Lawrence A. Daellenbach: associate professor, University of Wisconsin, La Crosse, Aug. 28, 1972.

Don J. DeVoretz: associate professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1971.

James Fenner: associate professor of economics, University of Bridgeport, Sept. 1972.

Richard Fryman: associate professor of economics, Southern Illinois University, July 1971.

William R. Graham: associate professor of economics and statistics, California State University, Los Angeles, Sept. 1972.

Margaret L. Greene: manager, foreign department, Federal Reserve Bank of New York.

Andrew C. Gross: associate professor, Cleveland State University, Sept. 1, 1971.

Harish C. Gupta: associate professor of economics, University of Nebraska, 1972–73.

Michael J. Hamburger: senior economist, research and statistics function, Federal Researve Bank of New York.

Judd Hammack: associate professor of economics and statistics, California State University, Los Angeles, Sept. 1972.

William B. Hartley: professor of economics, Iowa Wesleyan College, Sept. 1, 1972.

M. F. Hassan: professor of economics, Illinois State University.

F. Gregory Hayden: associate professor of economics, University of Nebraska, 1972–73.

Paul L. Helsing: professor, department of economics, Eastern Washington State College, May 1972.

Paul Heyne: professor, department of economics, Southern Methodist University, May 1972.

M. Bruce Johnson: professor of economics, University of California, Santa Barbara, July 1972.

Dennis R. Maki: associate professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1971.

Lloyd J. Mercer: associate professor of economics, University of California, Santa Barbara, July 1972.

Turley Mings: professor, economics department, California State University, San Jose, Sept. 1, 1972.

Paul T. Mu: associate professor of economics, California State University, Los Angeles, Sept. 1972.

Edgar O. Olsen: associate professor, department of economics, University of Virginia, Sept. 1, 1972.

Virginia L. Owen: associate professor of economics, Illinois State University.

Ramachandra Ramanathan: associate professor of economics, University of California, San Diego, July 1, 1972.

Edward J. Regan: chief, financial statistics division, Federal Reserve Bank of New York.

Nagesh S. Revankar: associate professor of economics, State University of New York at Buffalo.

Milton Russell: professor of economics, Southern Illinois University, June 1971.

William B. Simpson: professor of economics, California State University, Los Angeles, Sept. 1972.

Russell A. Snyder: professor of economics, Eastern Washington State College, Sept. 1972.

Kevin C. Sontheimer: associate professor of economics, State University of New York at Buffalo.

Gerald F. Sorrensen: associate professor of economics, California State University, Los Angeles, Sept. 1972.

Gary Stern: chief, business conditions division, Federal Reserve Bank of New York.

Robert C. Stuart: associate professor of economics, Douglass College, Rutgers University, July 1, 1972.

Sam Sydneysmith: associate professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1972.

Arlon R. Tussing: professor, University of Alaska, July 1972.

Harold L. Votey, Jr.: associate professor of economics, University of California, Santa Barbara, July 1972.

William C. Wedley: assistant professor, department of economics and commerce, Simon Fraser University, August 25, 1971.

Administrative Appointments

Alec P. Alexander: dean, College of Letters and Science, University of California, Santa Barbara, July 1971.

A. Paul Ballantyne: dean, College of Letters, Arts, and Sciences, University of Colorado, Apr. 1972.

Parzival Copes: chairman, department of economics and commerce, Simon Fraser University, Sept. 1, 1972.

John Drake, University of Washington: chairman, department of world business, Thunderbird Graduate School, Sept. 1972.

John S. Dydo: director, administrative studies program, Southampton College of Long Island University, July 25, 1972.

Edna E. Ehrlich: manager, international research department, Federal Reserve Bank of New York.

Marshall I. Goldman: chairman, department of economics, Wellesley College, Sept. 1971.

William B. Hartley: chairman, department of economics and business administration, Iowa Wesleyan College, Sept. 1, 1972.

John B. Henderson: chief, economics division, Congressional Research Service, Library of Congress, Sept. 1972.

Frank I. Jewett: associate dean for instructional resources, California State University, Humboldt, July 1, 1972.

Stanley R. Johnson: chairman, department of economics, University of Missouri, Columbia, July 1, 1972.

Carl R. Jones: associate chairman (academic planning and instruction), department of operations research and administrative sciences, Naval Postgraduate School, July 1971.

James V. Koch: chairman, department of economics, Illinois State University.

Stephen J. Kohn, Akron National Bank & Trust Company: superintendent of banks, State of Ohio, Nov. 1, 1972.

David H. Kopf: chief, money and finance division, Federal Reserve Bank of New York.

Cletus H. Kruyer, Jr. vice-president of college affairs, High Point College.

Robert G. Layer: chairman, department of economics Southern Illinois University, Feb. 1, 1972.

Lloyd J. Mercer: vice-chairman, department of economics, University of California, Santa Barbara, July 1972.

Turley Mings: director, Center for Economics Education, California State University, San Jose, Sept. 1, 1972.

Gordon A. Philpot: chairman, department of economics, Whitman College, June 1, 1972.

Alfred E. Pierce: acting head, department of economics and business, Lafayette College, Aug. 1, 1972.

John E. Rapp, MacMurray College: professor of economics and chairman, University of Dayton, Aug. 1972.

George Rosen: head, department of economics, University of Illinois, Chicago Circle, Sept. 1972.

John B. Ross: vice-president, Bank of America, San Francisco, Oct. 18, 1972.

William R. Russell: chairman, department of economics, Southern Methodist University, June 1972.

George G. Sause: provost, Lafayette College, Aug. 1, 1972.

Richard T. Selden: chairman, department of economics, University of Virginia, Sept. 1, 1972.

Malcolm F. Severance, acting chairman, department of economics and business administration, University of Vermont, July 1, 1972.

Jerome B. Siebert: associate director, Agricultural Extension, University of California at Berkeley, Sept. 1, 1972.

Russell A. Snyder: chairman, department of economics, Eastern Washington State College, Sept. 1972.

Douglas P. Sweetland: department chairman, department of economics, University of Wisconsin, La Crosse, Aug. 28, 1972.

Harold L. Votey, Jr.: acting director, Center for the Study of Developing Nations and the Community and Organizations Research Institute, University of California, Santa Barbara, July 1971.

Richard L. Wallace: director of Policy Research Center and assistant dean for research, College of Administration and Public Affairs, University of Missouri, Columbia.

W. Donald Wood, director, Industrial Relations Center, Queen's University: acting chairman, Ontario Economic Council.

New Appointments

Roy D. Adams: assistant professor of economics, Iowa State University.

Rahim Amin, University of Cincinnati: assistant professor of economics, Anderson College, Sept. 1972.

Geoffrey T. Andron: visiting assistant professor of economics, Iowa State University, 1972–73.

Richard K. Armey, Austin College: associate professor of economics, North Texas State University, Sept. 1, 1972.

Richard W. Ault, University of Virginia: lecturer, Texas A&M University.

Raveendra N. Batra, University of Western Ontario: associate professor, department of economics, Southern Methodist University, Sept. 1972.

Edward I. Beck: instructor, department of economics and business, Lafayette College, Sept. 1. 1972.

R. A. Douglas Beck, Iowa State University: assistant professor, department of economics and commerce, Simon Fraser University, Sept. 28, 1972.

Sohrab Behdad, Michigan State University: lecturer, Syracuse University, 1972–73.

David A. Belsley: senior research associate, National Bureau of Economic Research, Computer Research Center.

Robert L. Bish, University of Washington: associate professor, department of economics and Center for Urban Affairs, University of Southern California, Sept. 1972.

Tapan K. Biswas: lecturer, department of economics, University of California, Santa Barbara, July 1972.

Charles Blackorby, London School of Economics: associate professor of economics, Southern Illinois University, Sept. 1972.

Michael K. Block, University of Santa Clara: assistant professor of economics, Naval Postgraduate School, Sept. 1972.

Gregory S. Boussios: assistant professor of economics, Southampton College of Long Island University, Sept. 1, 1972.

D. L. Brito, University of Wisconsin: associate professor, The Ohio State University.

Robert Brownlee: instructor, Syracuse University, Sept. 1972–73.

David C Bunting: visiting assistant professor, department of economics, Eastern Washington State College, Sept. 1972.

Stephen Buser, Boston College: assistant professor of economics, Southern Illinois University, Sept. 1972.

Tansu U. Ciller, University of Connecticut: assistant professor of economics, Franklin and Marshall College, Sept. 1972.

Charles E. Conrod, Northwestern University: visiting instructor, Simon Fraser University, Sept. 1, 1972.

John S. Cook, Purdue University: assistant professor, department of economics, University of South Carolina.

L. Jorn Dakin, University of Kansas: assistant professor of economics and business law, University of North Florida, Sept. 1972.

Martin Davis: assistant professor, economics department, California State University, San Jose, Sept. 1, 1972.

Robert T. Deacon: assistant professor of economics, University of California, Santa Barbara, July 1972.

Merrill E. Douglass: assistant professor of business administration, Emory University, Sept. 1, 1972.

Douglas Dowd: lecturer, economics department, California State University, San Jose, Sept. 1, 1972.

John S. Dydo, C.R. Dean Economics, Inc.: professor of economics, Southampton College of Long Island University, July 1, 1972.

Randyl D. Elkin: visiting assistant professor of economics, Iowa State University, 1972–73.

Howard Elliott, Princeton University: research associate, Center for Research on Economic Development, University of Michigan.

James Elliott, Yale University: research associate,

Center for Research on Economic Development, University of Michigan.

Thomas W. Epps, U.S. Army: assistant professor, department of economics, University of Virginia, Sept. 1, 1972.

Teviah L. Estrin: instructor, department of economics and commerce, Simon Fraser University, Sept. 1, 1972.

Bert Evans: associate professor of economics, University of Nebraska, 1972–73.

Roger N. Folsom, Claremont Graduate School: assistant professor of economics, Naval Postgraduate School, Sept. 1972.

Ralph R. Frasca, Indiana University: assistant professor of economics, University of Dayton, Aug. 1972.

Stuart A. Gallaher: instructor, department of economics and business, Lafayette College, Sept. 1, 1972.

Gillian G. Garcia: assistant professor, economics department, California State University, San Jose, Sept. 1, 1972.

Marshall Geer, University of Colorado: associate professor of economics, Thunderbird Graduate School, Sept. 1972.

Charles G. Geiss: assistant professor of economics, University of Missouri, Columbia.

Betty Gibson: lecturer, economics department, California State University, San Jose, Sept. 1, 1972.

Errol Glustoff, University of Tennessee: visiting associate professor, department of economics, University of California, Santa Barbara, 1972–73.

Robert S. Golden: assistant professor of economics and statistics, California State University, Los Angeles, Sept. 1972.

Loretta L. Good: assistant professor, University of Wisconsin, La Crosse, Aug. 1972.

Hans-Werner Gottinger: lecturer, department of economics, University of California, Santa Barbara, Jan. 1973.

Levern Graves, California State University, Fullerton: visiting professor, California State University, Los Angeles, summer 1972.

Ronald E. Grieson, Massachusetts Institute of Technology: assistant professor, Queens College, City University of New York, 1972–73.

Reuben Gronau: research associate, National Bureau of Economic Research, June 1972.

Arthur Guthrie, Carleton University: assistant professor, department of economics and commerce, Simon Fraser University, Jan. 1, 1973.

Josef Hadar, Case Western Reserve University: professor, department of economics, Southern Methodist University, Sept. 1972.

Gus W. Haggstrom, University of California, Berkeley: staff member, economics department, The Rand Corporation, Aug. 1972.

Bennett Harrison, University of Maryland: associate professor of economics and urban studies, Massachusetts Institute of Technology, Mar. 1973.

Jacob Hornik: assistant professor, department of marketing, University of Illinois at Chicago Circle.

Ernest L. Inwood, California State University, San Jose: professor, economics department, Eastern College, Sept. 1, 1972.

J. Mark Jackson, Auburn University: visiting assistant professor, Texas A&M University.

John A. James, Massachusetts Institute of Technology: acting assistant professor, department of economics, University of Virginia, Feb. 1, 1973.

Karen Johnson, Massachusetts Institute of Technology: instructor, Wellesley College, Sept. 1971.

William A. Johnson, Rand Corporation: staff economist, Council of Economic Advisers.

Suhas Ketkar, Vanderbilt University: lecturer, University of Sierra Leone and research associate, Center for Research on Economic Development, University of Michigan.

Larry Kiser: assistant professor, department of economics, Eastern Washington State College, Sept. 1972.

Odin K. Knudsen: lecturer, economics department, California State University, San Jose, Sept. 1, 1972.

James V. Koch, Northern Illinois University: visiting associate professor, California State University, Los Angeles, summer 1972.

Robert Konwea, California State University, San Jose: visiting assistant professor, California State University, Los Angeles, summer 1972.

John D. Kyle: visiting associate professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1972.

William K. Kyle: assistant professor of administration, Sangamon State University, fall 1972.

Helen Ladd, Harvard University: instructor, Wellesley College, Sept. 1971.

Harvey E. Lapan: assistant professor of economics, Iowa State University.

Norman B. Lefton: consultant economist in medical affairs, Regional Medical Program of Hawaii, Sept. 1972.

Roger C. Leonhard: instructor, department of economics, University of Virginia, Sept. 1, 1972.

Dianne R. Levene: assistant professor of economics, California State University, Los Angeles, Sept. 1972.

Wilbur C. Lewellen: research associate, National Bureau of Economic Research, July 1972.

Lee A. Lillard: research associate, National Bureau of Economic Research, June 1972.

Thomas J. Lombardo, Texas Tech University: assistant director, Center for Economic Education, North Texas State University, July 1, 1972.

Edwin J. Longfellow: instructor, department of economics, Iowa State University.

Richard E. Low, Rutgers University: visiting associate professor, California State University, Los Angeles, summer 1972.

Dennis A. MacDonneil, University of California, Riverside: international training officer, Bank of America, July 1972.

Peter J. McCabe: acting assistant professor of economics, University of California, Santa Barbara, July 1971.

John M. Marshall, Vanderbilt University: assistant professor of economics, University of California, Santa Barbara, July 1972.

James C. Miller III, U.S. Department of Transporta-

tion: associate professor, Texas A&M University.

Kenneth E. Moberg: assistant professor of business administration, Emory University, Sept. 1, 1972.

Terry Monson, University of Minnesota: research associate, Center for Research on Economic Development, University of Michigan.

Peter Moock, Columbia University: research associate, Center for Research on Economic Development, University of Michigan.

R. Allen Moran: assistant professor of economics, University of Bridgeport, Sept. 1972.

James A. Morris: professor, department of economics, University of South Carolina.

Alexander L. Morton: research associate, National Bureau of Economic Research, Aug. 1972.

Milton Moss: senior research associate, National Bureau of Economic Research, May 1972.

Dennis C. Mueller: research associate, National Bureau of Economic Research, Aug. 1972.

Paul Munyon, Harvard University: instructor, Wellesley College, Sept. 1971.

Dennis D. Olson: assistant professor of economics, Emory University, 1972–73.

Gerald W. Olson: instructor, department of economics, University of Missouri, Kansas City, Sept. 1, 1971.

Andrew Parnes: lecturer, economics department, California State University, San Jose, Sept. 1, 1972.

Newman S. Peery: instructor, department of economics and commerce, Simon Fraser University, Sept. 1, 1972.

Neal Pepper, economist, money and finance division, Federal Reserve Bank of New York.

Lawrence T. Pinfield, Stanford University: assistant professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1972.

Perry W. Polk: instructor, department of economics and management, USAF Academy, June 1972.

Nikolai Pulchritudoff: assistant professor of economics and statistics, California State University, Los Angeles, Sept. 1972.

Theodore E. Quast, Jr., Indiana University, South Bend; assistant professor of economics, Marshall University, Aug. 28, 1972.

Satish Raichur, University of Pittsburgh: visiting assistant professor, Graduate School of International Studies, University of Denver.

Samuel D. Ramenofsky: assistant professor, department of economics, University of Missouri, Kansas City, Sept. 1, 1972.

Clyde G. Reed, University of Washington: assistant professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1972.

Edward H. Robb: assistant professor of economics and director of the State and Regional Fiscal Studies Unit, University of Missouri, Columbia, July 1, 1972.

John D. Rossi: assistant professor, department of economics and business, Lafayette College, Sept. 1, 1972.

R. S. Rungta: visiting associate professor of marketing, Temple University, 1972–73.

Gertrude E. Schroeder: professor, department of economics, University of Virginia, Sept. 1, 1972.

Richard Schwindt: instructor, department of economics and commerce, Simon Fraser University, Sept. 1, 1972.

Ernest M. Scott: instructor, department of economics and commerce, Simon Fraser University, Sept. 1, 1972.

Gerald W. Scully, Southern Illinois University: associate professor, department of economics, Southern Methodist University, Sept. 1972.

M. Sabry El Shabrawy, University of Illinois: assistant professor of world business, Thunderbird Graduate School, Sept. 1972.

Jeremy F. Shapiro: senior research associate, National Bureau of Economic Research, Computer Research Center, July 1972.

Kenneth Shapiro, Stanford University: research associate, Center for Research on Economic Development, University of Michigan.

Stephen L. Shapiro, University of South Carolina: assistant professor of economics, University of North Florida, Aug. 1972.

James F. Smith: research associate, National Bureau of Economic Research, Oct. 1972.

John C. Soper, University of Missouri, Columbia: assistant professor of economics and coordinator, office for economic education, Northern Illinois University, Sept. 1972.

Gayle Southworth: lecturer, economics department, California State University, San Jose, Sept. 1, 1972.

Earl O. Stephens: assistant professor of economics and statistics, California State University, Los Angeles, Sept. 1972.

Wayne L. Stevenson: assistant professor, department of economics, Middlebury College, Sept. 1972.

George J. Stigler: senior research staff, National Bureau of Economic Research, July 1972.

Raymond J. Struyk, Rice University: Housing Studies Group, The Urban Institute, May 1972.

William J. Taylor: lecturer in business administration, Emory University, 1972–73.

Katsuaki Terasawa, California Institute of Technology: assistant professor of economics, Naval Postgraduate School, June 1972.

Harriet Tolpin, Boston College: instructor, Wellesley College, Jan 1973.

Edward Tower, University of Auckland: assistant professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1972.

Andris Trappens, University of California, Berkeley: assistant professor of economics, Thunderbird Graduate School, Feb. 1973.

Roger Van Tassel, Clark University: visiting professor, California State University, Los Angeles, summer 1972.

Roger C. Vergin, University of Washington: professor, department of economics and commerce, Simon Fraser University, Sept. 1, 1972.

Robert Vogel, Wesleyan University: associate professor of economics, Southern Illinois University, Sept. 1972.

Dale Vorderlandwehr, Michigan State University: assistant professor of economics, Thunderbird Graduate School, Sept. 1972.

Janice Weaver, University of Illinois: lecturer, Syracuse University, 1972–73.

Rodger Weaver: assistant professor of economics, University of Nebraska, 1972–73.

Charles L. Weber: lecturer, department of economics, University of Illinois, Chicago Circle.

William E. Wehrs: assistant professor, University of Wisconsin, La Crosse, Aug. 1972.

Peter Weisel, University of Oregon: research associate, Center for Research on Economic Development, University of Michigan.

Joseph Weiss, Louis Berger, Inc.: marketing economist, Companhia Brasileira de Alimentos, Brasilia, Oct. 15, 1972.

Donald R. Winkler: assistant professor of economics, University of California, Santa Barbara, July 1972.

Louis A. Woods, East Carolina University: assistant professor of geography and economics, University of North Florida, fall 1972.

Paul Zarembka, University of California, Berkeley: associate professor of economics, State University of New York at Buffalo.

Seid M. Zekavat, Loyola University of Los Angeles: visiting associate professor, California State University, Los Angeles, summer 1972.

Leaves for Special Appointments

Albert Y. Badre, Southern Illinois University: professor of economics, American University, Beirut, 1971–72.

Abraham S. Becker, The Rand Corporation: visiting professor of economics, Soviet and East European Research Center, Hebrew University, 1972–73.

James W. Christian, Iowa State University: Federal Home Loan Bank Board, Washington, Sept. 1, 1972–Aug. 31, 1973.

Michael R. Darby, Ohio State University: visiting assistant professor, University of California, Los Angeles.

William B. Eastlake, Boise State College: Fulbright lecturer in economics, Cuttington College, Monrovia, Liberia, July 1971–July 1973.

Milton Edelman, Southern Illinois University: Fulbright research scholar, Industrial Relations Research Unit, Social Science Research Council, University of Warwick, England, Jan.–June 1973.

Julian M. Greene, Southern Methodist University: Ernst and Ernst, MCS Division, Washington, Aug. 1972.

Geoffrey B. Hainsworth, University of British Columbia: research associate, International Development Research Council, Ottawa, 1972–73; visiting fellow, Overseas Development Council, Washington, Jan.–June 1973.

Yukon Huang, University of Virginia: University of Dar es Salaam, Dar es Salaam, Tanzania, 1972–74.

John Kraft, University of Florida: Brookings Institution Economic Policy Fellow, Brookings Institution and the Price Commission, June 1972.

Fred D. Levy, Jr., Syracuse University: U.S. Treasury, July 1972.

Katharine C. Lyall, Syracuse University: senior research associate, Center for Urban Studies, Johns Hopkins University, Sept. 1972.

Richard C. Maxon, Iowa State University: senior visiting lecturer, department of agricultural economics, University of Ibadan, Ibadan, Nigeria, Sept. 1, 1972–Aug. 31, 1973.

Walter J. Mead, University of California, Santa Barbara: chief economist, The Energy Policy Project, Washington, Sept. 1, 1972–Aug. 31, 1973.

John C. Murdock, University of Missouri, Columbia: professor of economics and adviser to the graduate dean, Massey University, New Zealand, Sept. 1972.

James R. O'Connor, California State University, San Jose: Max Planck Institut, West Germany, fall 1972.

Richard L. Peterson, Southern Methodist University: Consumer Credit and Finance Section, Division of Research and Statistics, Federal Reserve Board, Aug. 1972.

R. Robert Russell, University of California, Santa Barbara: visiting associate professor of economics, University of California, San Diego, 1972–73.

Kevin C. Sontheimer, State University of New York, Buffalo: visiting associate professor of mathematical economics, Naval Postgraduate School, 1973.

Charles Stokes, University of Bridgeport: General Accounting Office, Washington.

P. A. V. B. Swamy, Ohio State University: consultant with the Board of Governors, Federal Reserve System, Washington.

Richard S. Thorn, University of Pittsburgh: visiting professor, University of Aix-Marseille, Oct. 1972; University of Paris, Feb. 1973.

Sue Van Atta, California State University, San Jose: School of Business, University of California, Berkeley, Sept. 1, 1972.

Barbara S. Zoloth, Emory University: Fellow, Brookings Institution, 1972–73.

Resignations

Kirk Blackerby, California State University, San Jose, June 30, 1972.

Arthur E. Gandolfi, Federal Reserve Bank of New York: First National City Bank.

Donald M. Lamberton, Case Western Reserve University: University of Queensland, Jan. 1973.

David R. Miller, Syracuse University: Barton-Aschman Associates, Chicago, Sept. 1972.

Ronald L. Moomaw, University of Virginia, June 30, 1972.

David V. Pritchett, Federal Reserve Bank of New York: First National City Bank.

Rachel Strauber, Federal Reserve Bank of New York.

James B. Thornblade, Syracuse University: First National Bank of Boston, Sept. 1972.

Peter G. Van der Spek, Federal Reserve Bank of New York: Overseas Business Expansion.

• Published at George Banta Co., Inc., Menasha, Wisconsin.

• THE AMERICAN ECONOMIC REVIEW, including four quarterly numbers, the *Proceedings* of the annual meetings, and *Directory* and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September, and December.

• Membership dues of the Association are $20.00 a year, which includes a year's subscription to both the *American Economic Review* and the *Journal of Economic Literature.* A three year junior membership of $10.00 per year is available to registered students. Subscriptions by nonmembers are $30.00 a year, and only subscriptions to both publications will be accepted. Single copies of the *Review* and *Journal* are $4.00 each. Each order for copies of either publication must also include a $.50 per order service charge. Orders should be sent to the Secretary's office, Nashville, Tennessee.

• Correspondence relating to the *Papers and Proceedings,* the *Directory,* advertising, permission to quote, business matters, subscriptions, membership and changes of address may be sent to the secretary, Rendigs Fels, 1313 21st Avenue, South, Nashville, Tennessee 37212. To be effective, notice of change of address must reach the secretary by the 1st of the month previous to the month of publication. The Association's publications are mailed by second class and are not forwardable by the Post Office.

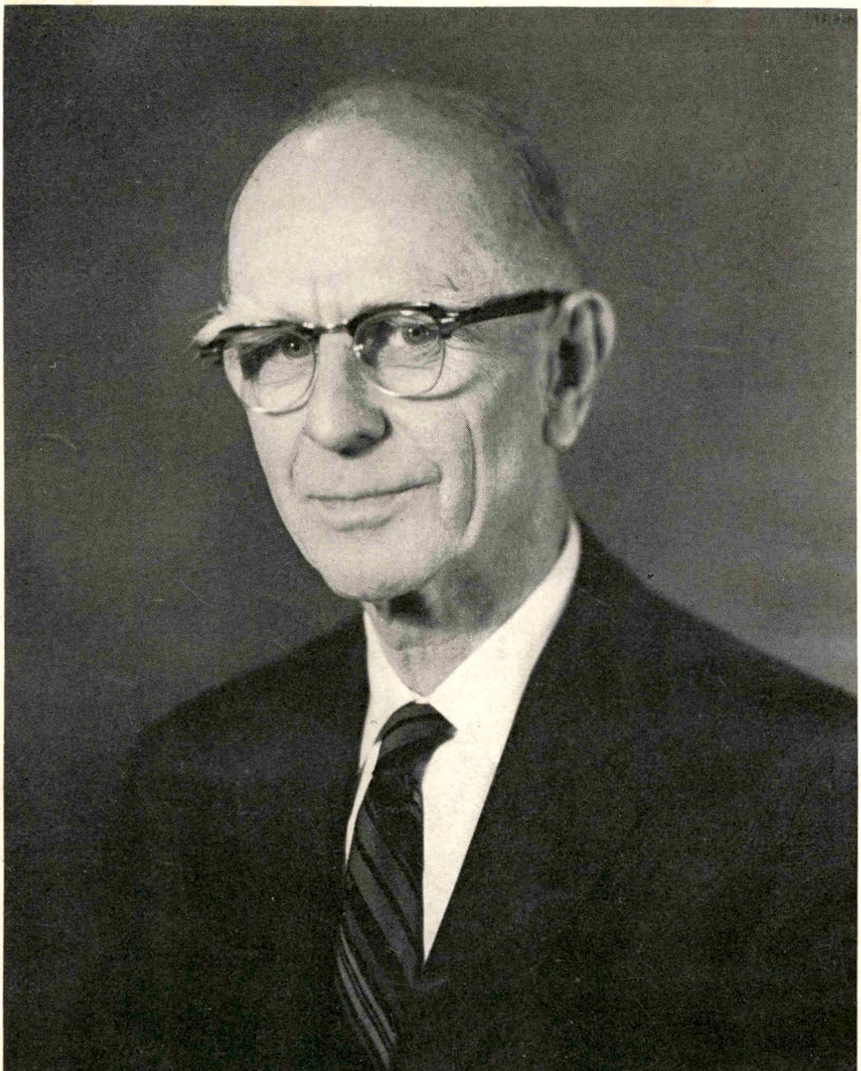
• Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.

CARL S. SHOUP

Distinguished Fellow

1972

Carl Sherman Shoup's distinguished contributions to public finance range from pure tax theory to the history of thought on taxation and practical tax reform. His reputation derives in large part from his studies of the turnover tax, tax harmonization among common market countries, and estate taxation. In addition, he was the principal architect of ingenious and detailed tax reform proposals for Japan and Venezuela. His recent treatise, *Public Finance,* is a work of major significance that brings together his contributions to economic theory and applied economics during the past forty years.



Carl S. Strong

Modern Economic Growth: Findings and Reflections

By SIMON KUZNETS*

I. Definitions

A country's economic growth may be defined as a long-term rise in capacity to supply increasingly diverse economic goods to its population, this growing capacity based on advancing technology and the institutional and ideological adjustments that it demands. All three components of the definition are important. The sustained rise in the supply of goods is the *result* of economic growth, by which it is identified. Some small countries can provide increasing income to their populations because they happen to possess a resource (minerals, location, etc.) exploitable by more developed nations, that yields a large and increasing rent. Despite intriguing analytical problems that these few fortunate countries raise, we are interested here only in the nations that derive abundance by using advanced contemporary technology—not by selling fortuitous gifts of nature to others. Advancing technology is the *permissive* source of economic growth, but it is only a potential, a necessary condition, in itself not sufficient. If technology is to be employed efficiently and widely, and, indeed, if its own progress is to be stimulated by such use, institutional and ideological adjustments must be made to effect the proper use of innovations generated by the advancing stock of human knowledge. To cite examples from modern economic growth: steam and electric power and the large-scale plants needed to exploit them are not compatible with family enterprise, illiteracy, or slavery—all of which prevailed in earlier times over much of even the developed world, and had to be replaced by more appropriate institutions and social views. Nor is modern technology compatible with the rural mode of life, the large and extended family pattern, and veneration of undisturbed nature.

The source of technological progress, the particular production sectors that it affected most, and the pace at which it and economic growth advanced, differed over centuries and among regions of the world; and so did the institutional and ideological adjustments in their interplay with the technological changes introduced into and diffused through the growing economies. The major breakthroughs in the advance of human knowledge, those that constituted dominant sources of sustained growth over long periods and spread to a substantial part of the world, may be termed epochal innovations. And the changing course of economic history can perhaps be subdivided into economic epochs, each identified by the epochal innovation with the distinctive characteristics of growth that it generated.[1] Without considering the feasibility of identifying and dating such economic epochs, we may proceed on the working assumption that modern economic growth represents such a

[1] For a discussion of the economic epoch concept, see Kuznets (1966), pp. 1–16.

distinct epoch—growth dating back to the late eighteenth century and limited (except in significant *partial* effects) to economically developed countries. These countries, so classified because they have managed to take adequate advantage of the potential of modern technology, include most of Europe, the overseas offshoots of Western Europe, and Japan—barely one quarter of world population.[2] This paper will focus on modern economic growth, but with obviously needed attention to its worldwide impact.

Limitations of space prevent the presentation of a documented summary of the quantitative characteristics commonly observed in the growth of the presently developed countries, characteristics different from those of economic growth in earlier epochs. However, some of them are listed, because they contribute to our understanding of the distinctive problems of economic life in the world today. While the list is selective and is open to charges of omission, it includes those observed and empirically testable characteristics that lead back to some basic factors and conditions, which can only be glimpsed and conjectured, and forward to some implications that have so far eluded measurement.

II. The Six Characteristics

Six characteristics of modern economic growth have emerged in the analysis based on conventional measures of national product and its components, population, labor force, and the like. First and most obvious are the high rates of growth of per capita product and of population in the developed countries—both large multiples of the previous rates observable in these countries and of those in the rest of the world, at least until the recent decade or two.[3] Second, the rate of rise in productivity, i.e., of output per unit of all inputs, is high, even when we include among inputs other factors in addition to labor, the major productive factor—and here too the rate is a large multiple of the rate in the past.[4] Third, the rate of structural transformation of the economy is high. Major aspects of structural change include the shift away from agriculture to nonagricultural pursuits and, recently, away from industry to services; a change in the scale of productive units, and a related shift from personal enterprise to impersonal organization of economic firms, with a corresponding change in the occupational status of labor.[5]

[2] For a recent classification identifying the non-Communist developed countries, see United Nations *Yearbook*, notes to Table 5, p. 156. These classifications vary from time to time, and differ somewhat from those of other international agencies.

[3] For the non-Communist developed countries, the rates of growth per year over the period of modern economic growth, were almost 2 percent for product per capita, 1 percent for population, and 3 percent for total product. These rates—which mean roughly a multiplication over a century by five for product per capita, by three for population, and by more than fifteen for total product—were far greater than premodern rates. The latter can only be conjectured, but reasonable estimates for Western Europe over the long period from the early Middle Ages to the mid-nineteenth century suggest that the modern rate of growth is about ten times as high for product per capita (see Kuznets (1971), pp. 10–27). A similar comparison for population, either for Europe or for the area of European settlement (i.e., Europe, the Americas, and Oceania), relating to 1850–1960, as compared with 1000–1850, suggests a multiple of 4 or 5 to 1 (see Kuznets (1966), Tables 2.1 and 2.2, pp. 35 and 38). The implied acceleration in the growth rate of total product is between forty and fifty times.

[4] Using the conventional national economic accounts, we find that the rate of increase in productivity is large enough to account (in the statistical sense) for almost the entire growth of product per capita. Even with adjustments to allow for hidden costs and inputs, growth in productivity accounts for over half of the growth in product per capita (see Kuznets (1971), pp. 51–75, particularly Table 9, p. 74; and Table 11, p. 93).

[5] The rapidity of structural shifts in modern times can be easily illustrated by the changes in the distribution of the labor force between agriculture (and related industries) and the nonagricultural production sectors. In the United States, the share of labor force attached to the agricultural sector was still 53.5 percent in 1870 and declined to less than 7 percent in 1960. In an old European country like Belgium, the share of agriculture in the labor force, 51 percent in 1846, dropped to 12.5 percent in 1947 and further to 7.5 percent in 1961 (see Bairoch et al., Tables D-4 and C-4). Considering that it

Shifts in several other aspects of economic structure could be added (in the structure of consumption, in the relative shares of domestic and foreign supplies, etc.). Fourth, the closely related and extremely important structures of society and its ideology have also changed rapidly. Urbanization and secularization come easily to mind as components of what sociologists term the process of modernization. Fifth, the economically developed countries, by means of the increased power of technology, particularly in transport and communication (both peaceful and warlike), have the propensity to reach out to the rest of the world—thus making for one world in the sense in which this was not true in any premodern epoch.[6] Sixth, the spread of modern economic growth, despite its worldwide partial effects, is limited in that the economic performance in countries accounting for three-quarters of world population still falls far short of the minimum levels feasible with the potential of modern technology.[7]

This brief summary of two quantitative characteristics of modern economic growth that relate to aggregate rates, two that relate to structural transformation, and two that relate to international spread, supports our working assumption that modern economic growth marks a distinct economic epoch. If the rates of aggregate growth and the speed of structural transformation in the economic, institutional, and perhaps even in the ideological, framework are so much higher than in the past as to represent a revolutionary acceleration, and if the various regions of the world are for the first time in history so closely interrelated as to be one, some new major growth source, some new epochal innovation, must have generated these radically different patterns. And one may argue that this source is the emergence of modern science as the basis of advancing technology—a breakthrough in the evolution of science that produced a potential for technology far greater than existed previously.

Yet modern growth continues many older trends, if in greatly accelerated form. This continuity is important particularly when we find that, except for Japan and possibly Russia, all presently developed countries were well in advance of the rest of the world before their modern growth and industrialization began, enjoying a comparative advantage produced by premodern trends. It is also important because it emphasizes that distinction among economic epochs is a complicated intellectual choice and that the continuation of past trends and their changing patterns over time are subjects deserving the closest attention. Does the acceleration in growth of product and productivity in many developed countries in the last two decades reflect a major change in the potential provided by science-oriented technology, or a major change in the capacity of societies to catch up with that potential? Is it a way of recouping the loss in standing, relative to such a leader as the United States, that was incurred during the depression of the 1930's and World War II? Or, finally, is it merely a reflection of the temporarily favorable climate of the *U.S.* international policies? Is the expansion into space a continuation of the old trend

took centuries for the share of the agricultural sector in the labor force to decline to 50 percent in any sizable country (i.e., excluding small "city enclaves"), a drop of 30 to 40 percentage points in the course of a single century is a strikingly fast structural change.

[6] The outward expansion of developed countries, with their European origin, goes back to long before modern economic growth, indeed, back to the Crusades. But the much augmented transportation and communication power of developed countries in the nineteenth century permitted a much greater and more direct political dominance over the colonies, the "opening up" of previously closed areas (such as Japan), and the "partition" of previously undivided areas (such as sub-Saharan Africa).

[7] For further discussion see Section IV below, which deals with the less developed countries.

of reaching out by the developed countries, or is it a precursor of a new economic epoch? These questions are clearly illustrative, but they hint at broader analytical problems suggested by the observation of modern economic growth as a distinct epoch.

The six characteristics noted are interrelated, and the interrelations among them are most significant. With the rather stable ratio of labor force to total population, a high rate of increase in per capita product means a high rate of increase in product per worker; and, with average hours of work declining, it means still higher growth rates in product per man-hour. Even if we allow for the impressive accumulation of capital, in its widest sense, the growth rate of productivity is high, and, indeed, mirrors the great rise in per capita product and in per capita pure consumption. Since the latter reflects the realized effects of advancing technology, rapid changes in production structure are inevitable—given the differential impact of technological innovations on the several production sectors, the differing income elasticity of domestic demand for various consumer goods, and the changing comparative advantage in foreign trade. As already indicated, advancing technology changes the scale of production plants and the character of the economic enterprise units. Consequently, effective participation in the modern economic system by the labor force necessitates rapid changes in its location and structure, in the relations among occupational status groups, and even in the relations between labor force and total population (the last, however, within narrow overall limits). Thus, not only are high aggregate growth rates associated with rapid changes in economic structure, but the latter are also associated with rapid changes in other aspects of society—in family formation, in urbanization, in man's views on his role and the measure of his achievement in society. The dynamic drives of modern economic growth, in the countries that entered the process ahead of others, meant a reaching out geographically; and the sequential spread of the process, facilitated by major changes in transport and communication, meant a continuous expansion to the less developed areas. At the same time, the difficulty of making the institutional and ideological transformations needed to convert the new large potential of modern technology into economic growth in the relatively short period since the late eighteenth century limited the spread of the system. Moreover, obstacles to such transformation were, and still are being, imposed on the less developed regions by the policies of the developed countries.

If the characteristics of modern economic growth are interrelated, in that one induces another in a cause and effect sequence or all are concurrent effects of a common set of underlying factors, another plausible and significant link should be noted Mass application of technological innovations, which constitutes much of the distinctive substance of modern economic growth, is closely connected with the further progress of science, in its turn the basis for additional advance in technology. While this topic is still to be studied in depth, it seems fairly clear that mass-uses of technical innovations (many based on recent scientific discoveries) provide a positive feedback. Not only do they provide a larger economic surplus for basic and applied research with long time leads and heavy capital demands, but, more specifically, they permit the development of new efficient tools for scientific use and supply new data on the behavior of natural processes under the stress of modification in economic production. In other words, many production plants in developed countries can be viewed as laboratories for the exploration of natural processes and as

centers of research on new tools, both of which are of immense service to basic and applied research in science and technology. It is no accident that the last two centuries were also periods of enormous acceleration in the contribution to the stock of useful knowledge by basic and applied research—which provided additional stimuli to new technological innovations. Thus, modern economic growth reflects an interrelation that sustains the high rate of advance through the feedback from mass applications to further knowledge. And unless some obstacles intervene, it provides a mechanism for self-sustaining technological advance, to which, given the wide expanse of the universe (relative to mankind on this planet), there are no obvious proximate limits.

III. Some Implications[8]

I turn now to a brief discussion of some social implications, of some effects of modern economic growth on conditions of life of various population groups in the countries affected. Many of these effects are of particular interest, because they are not reflected in the current measures of economic growth; and the increasing realization of this shortcoming of the measures has stimulated lively discussion of the limits and limitations of economic measurement of economic growth.

The effects on conditions of life stem partly from the major role of technological innovations in modern economic growth, and partly from the rapid shifts in the underlying production structure. To begin with the latter, the major effects of which, for example, urbanization, internal migration, shift to employee status and what might be called the merit basis of job choice, have already been noted as characteristics of modern economic growth. Two important groups of effects of this rapid transformation of economic structure deserve explicit reference.

First, the changes in conditions of life suggested by "urbanization" clearly involved a variety of costs and returns that are not now included in economic measurement, and some of which may never be susceptible to measurement. Internal migration, from the countryside to the cities (within a country, and often international) represented substantial costs in the pulling up of roots and the adjustment to the anonymity and higher costs of urban living. The learning of new skills and the declining value of previously acquired skills was clearly a costly process—to both the individuals and to society. But if such costs were omitted from measurement, as they still are in conventional accounts, so were some returns. Urban life, with its denser population, provided amenities and spiritual goods that were not available in the "dull and brutish" life of the countryside; and the new skills, once learned, were often a more adequate basis for a richer life than the old. This comment on the hidden costs and returns involved in the shift toward urban life may apply to many other costs and returns involved in other shifts imposed by economic growth, for example, in the character of participation in economic activity, in the social values, and in the new pressures on deviant members of society.

The second intriguing aspect of structural change is that it represents shifts in the relative shares in the economy of the specific population groups attached to particular production sectors. Since economic engagement represents a dominant influence in the life of people, the shift in the share of a specific sector, with its distinctive characteristics and even mode of

[8] Many of the points touched upon in this section are discussed in greater dètail in Kuznets (1971), particularly in ch. 2, pp. 75–98, which deals with the nonconventional costs of economic growth, and ch. 7, pp. 314–54, which deals with various interrelations between aggregate change and structural shifts in economic and other aspects of social structure.

life, affects the population group engaged in it. Economic growth perforce brings about a decline in the relative position of one group after another—of farmers, of small scale producers, of landowners—a change not easily accepted, and, in fact, as history teaches us, often resisted. The continuous disturbance of preexisting *relative* position of the several economic groups is pregnant with conflict—despite the rises in absolute income or product common to all groups. In some cases, these conflicts did break out into overt civil war, the Civil War in the United States being a conspicuous example. Other examples, in the early periods of industrialization among the currently developed countries, or, for that matter, more recently within some less developed countries, are not lacking.

Only if such conflicts are resolved without excessive costs, and certainly without a long-term weakening of the political fabric of the society, is modern economic growth possible. The sovereign state, with authority based on loyalty and on a community of feeling—in short, the modern national state—plays a crucial role in peacefully resolving such growth-induced conflicts. But this and other services of the national state may be costly in various ways, of which intensified nationalism is one and other effects are too familiar to mention. The records of many developed countries reveal examples of resolutions of growth conflicts, of payments for overcoming resistance and obstacles to growth, that left burdensome heritages for the following generations (notably in Germany and Japan). Of course, this is not the only economic function of the state; it can also stimulate growth and structural change. And, to mention a closely related service, it can referee, select, or discard legal and institutional innovations that are proposed in the attempt to organize and channel effectively the new production potentialities. This, too, is a matter that may generate conflicts, since different legal and institutional arrangements may have different effects on the several economic groups in society.

In that modern economic growth has to contend with the resolution of incipient conflicts continuously generated by rapid changes in economic and social structure, it may be described as a process of controlled revolution. The succession of technological innovations characteristic of modern economic growth and the social innovations that provide the needed adjustments are major factors affecting economic and social structure. But these innovations have other effects that deserve explicit mention; and while they are discussed below in terms of effects of technological innovations, the conclusions apply *pari passu* to innovations in legal forms, in institutional structure, and even in ideology.

A technological innovation, particularly one based on a recent major invention, represents a venture into the partly unknown, something not fully known until the mass spread of the innovation reveals the full range of direct and related effects. An invention is a major one if it provides the basis for extensive applications and improvements (for example, the stationary steam engine in the form attributable mostly to James Watt). Its cumulative effects, all new, extend over a long period and result in an enormous transformation of economic production and of production relations. But these new effects can hardly be fully anticipated or properly evaluated in advance (and sometimes not even post facto). This is true also of electric power, the internal combustion engine, atomic energy, the application of short rays to communication and computation, the inventions resulting in such new industrial materials as steel, aluminum, and plastics, and so on through a long list that marked modern economic growth. Even when the

technological innovation is an adaptation of a known technique by a follower country, the results may not be fully foreseeable, for they represent the combination of something known, the technology, with something new, an institutional and ideological framework with which it has not previously been combined. Needless to say, the element of the uniquely new, of exploration into the unknown, was also prominent in premodern times, since innovations in knowledge and technology are the prerequisites for any significant growth. But the *rate* of succession of such innovations was clearly more rapid in modern economic growth, and provided the base for a higher rate of aggregate growth.

The effects of such ventures into the new and partly unknown are numerous. Those of most interest here are the *surprises*, the unexpected results, which may be positive or negative. An invention or innovation may prove far more productive, and induce a far wider mass application and many more cumulative improvements than were dreamed of by the inventor and the pioneer group of entrepreneurs. Or the mass application of a major invention may produce unexpected diseconomies of a scale that could hardly be foreseen in the early phases of its diffusion. Examples of both positive and negative surprises abound. Many Schumpeterian entrepreneurs failed to grasp, by a wide margin, the full scope and significance of the innovations that they were promoting and that eventually brought them fame and fortune. And most of us can point at the unexpected negative effects of some technological or social invention that first appeared to be an unlimited blessing.

The significant aspect here is that the surprises cannot be viewed as accidents: they are inherent in the process of technological (and social) innovation in that it contains an element of the unknown. Furthermore, the diffusion of a major innovation is a long and complicated sequence that cannot be accurately forecast, with an initial economic effect that may generate responses in other processes. These will, in turn, change the conditions under which the innovation exercises its effect on human welfare, and raise further problems of adjustment. To illustrate: we can today follow easily the sequence from the introduction of the passenger car as a mass means of transportation, to the growth of the suburbs, to the movement of the more affluent from the city centers, to the concentration of lower income recipients and unemployed immigrants in the slums of the inner city core, to the acute urban problems, financial and other, and to the trend toward metropolitan consolidation. But the nature and implications of this sequence were certainly not apparent in the 1920's, when passenger cars began their mass service function in the United States.

Indeed, to push this speculative line further, one can argue that all economic growth brings *some* unexpected results in its wake, positive as well as negative, with the latter taking on greater importance as the mass effects of major innovations are felt and the needs that they are meant to satisfy are met. If the argument is valid, modern economic growth, with the rapid succession of innovations and shortening period of their mass diffusion, must be accompanied by a relatively high incidence of negative effects. Yet one must not forget that premodern economic growth had similar problems, which, with the weaker technology, may have loomed even larger. Even if we disregard the threatening exhaustion of natural resources, a problem that so concerned Classical (and implicitly even Marxian) economics, and consider only early urbanization, one major negative effect was the significant rise in death rates as population moved from the more salubrious countryside to the infection-

prone denser conditions of unsanitary cities. Two points are relevant here. First, the negative effects of growth have never been viewed as so far outweighing its positive contribution as to lead to its renunciation—no matter how crude the underlying calculus may have been. Second, one may assume that once an unexpected negative result of growth emerges, the potential of material and social technology is aimed at its reduction or removal. In many cases these negative results were allowed to accumulate and to become serious technological or social problems because it was so difficult to foresee them early enough in the process to take effective preventive or ameliorative action. Even when such action was initiated, there may have been delay in the effective technological or policy solution. Still, one may justifiably argue, in the light of the history of economic growth, in which a succession of such unexpected negative results has been overcome, that any specific problem so generated will be temporary—although we shall never be free of them, no matter what economic development is attained.

IV. The Less Developed Countries

Two major groups of factors appear to have limited the spread of modern economic growth. First, as already suggested, such growth demands a stable, but flexible, political and social framework, capable of accommodating rapid structural change and resolving the conflicts that it generates, while encouraging the growth-promoting groups in society. Such a framework is not easily or rapidly attained, as evidenced by the long struggles toward it even in some of the presently developed countries in the nineteenth and early twentieth centuries. Japan is the only nation outside of those rooted in European civilization that has joined the group of developed countries so far. Emergence of a modern framework for economic growth may be especially difficult if it involves elements peculiar to European civilization for which substitutes are not easily found. Second, the increasingly national cast of organization in developed countries made for policies toward other parts of the world that, while introducing some modern economic and social elements, were, in many areas, clearly inhibiting. These policies ranged from the imposition of colonial status to other limitations on political freedom, and, as a result, political independence and removal of the inferior status of the native members of the community, rather than economic advance, were given top priority.

Whatever the weight of the several factors in explaining the failure of the less developed countries to take advantage of the potential of modern economic growth, a topic that, in its range from imperialist exploitation to backwardness of the native economic and social framework, lends itself to passionate and biased polemic, the factual findings are clear. At present, about two-thirds or more of world population is in the economically less developed group. Even more significant is the concentration of the population at the low end of the product per capita range. In 1965, the last year for which we have worldwide comparable product estimates, the per capita *GDP* (at market prices) of 1.72 billion out of a world total of 3.27 billion, was less than \$120, whereas 0.86 billion in economically developed countries had a per capita product of some \$1900. Even with this narrow definition of less developed countries, the intermediate group was less than 0.7 billion, or less than 20 percent of world population.[9] The preponderant

[9] The underlying data are from Everett Hagen and Oli Hawrylyshyn. These are primarily from United Nations publications, supplemented by some auxiliary sources (mostly for the Communist countries), and use conventional conversion rates to *U.S.* dollars in 1965. The estimates for the Communist countries have been adjusted to conform to the international *GDP* concept.

population was thus divided between the very low and the rather high level of per capita economic performance. Obviously, this aspect of modern economic growth deserves our greatest attention, and the fact that the quantitative data and our knowledge of the institutional structures of the less developed countries are, at the moment, far more limited than our knowledge of the developed areas, is not reason enough for us to ignore it.

Several preliminary findings, or rather plausible impressions, may be noted. First, the group of less developed countries, particularly if we widen it (as we should) to include those with a per capita product somewhat larger than $120 (in 1965 prices), covers an extremely wide range in size, in the relations between population and natural resources, in major inherited institutions, and in the past impact upon them of the developed countries (coming as it did at different times and from different sources). There is a striking contrast, for example, in terms of population size, between the giants like Mainland China and India, on the one hand, and the scores of tiny states in Africa and Latin America; as there is between the timing of direct Western impact on Africa and of that on many countries in Latin America. Furthermore, the remarkable institutions by which the Sinic and East Indian civilizations produced the unified, huge societies that dwarfed in size any that originated in Europe until recently. bore little resemblance to those that structured the American Indian societies or those that fashioned the numerous tribal societies of Africa.

Generalizations about less developed countries must be carefully and critically scrutinized in the light of this wide variety of conditions and institutions. To be sure, their common failure to exploit the potential of modern economic growth means several specific common features: a low per capita product, a large share of agriculture or other extractive industries, a generally small scale of production. But the specific parameters differ widely, and because the obstacles to growth may differ critically in their substance, they may suggest different policy directions.

Second, the growth position of the less developed countries today is significantly different, in many respects, from that of the presently developed countries on the eve of their entry into modern economic growth (with the possible exception of Japan, and one cannot be sure even of that). The less developed areas that account for the largest part of the world population today are at much lower per capita product levels than were the developed countries just before their industrialization; and the latter at that time were economically in advance of the rest of the world, not at the low end of the per capita product range. The very magnitudes, as well as some of the basic conditions, are quite different: no country that entered modern economic growth (except Russia) approached the size of India or China, or even of Pakistan and Indonesia; and no currently developed country had to adjust to the very high rates of natural increase of population that have characterized many less developed countries over the last two or three decades. Particularly before World War I, the older European countries, and to some extent even Japan, relieved some strains of industrialization by substantial emigration of the displaced population to areas with more favorable opportunities—an avenue closed to the populous less developed countries today. Of course, the stock of material and social technology that can be tapped by less developed countries today is enormously

The developed countries include most countries with per capita *GDP* of $1000 or more and Japan, but exclude those small countries with a high *GDP* per capita that is due to exceptional natural endowments (for example, Netherlands Antilles, Puerto Rico, Kuwait, and Qatar).

larger than that available in the nineteenth and even early twentieth centuries. But it is precisely this combination of greater backwardness and seemingly greater backlog of technology that makes for the significant differences between the growth position of the less developed countries today and that of the developed countries when they were entering the modern economic growth process.

Finally, it may well be that, despite the tremendous accumulation of material and social technology, the stock of innovations most suitable to the needs of the less developed countries is not too abundant. Even if one were to argue that progress in basic science may not be closely tied to the technological needs of the country of origin (and even that may be disputed), unquestionably the applied advances, the inventions and tools, are a response to the specific needs of the country within which they originate. This was certainly true of several major inventions associated with the Industrial Revolution in England, and illustrations abound of necessity as the mother of invention. To the extent that this is true, and that the conditions of production in the developed countries differed greatly from those in the populous less developed countries today, the material technology evolved in the developed countries may not supply the needed innovations. Nor is the social technology that evolved in the developed countries likely to provide models of institutions or arrangements suitable to the diverse institutional and population-size backgrounds of many less developed countries. Thus, modern technology with its emphasis on labor-saving inventions may not be suited to countries with a plethora of labor but a scarcity of other factors, such as land and water; and modern institutions, with their emphasis on personal responsibility and pursuit of economic interest, may not be suited to the more traditional life patterns of the agricultural communities that predominate in many less developed countries. These comments should not be interpreted as denying the value of many transferable parts of modern technology; they are merely intended to stress the possible shortage of material and social tools specifically fitted to the different needs of the less developed countries.

If the observations just made are valid, several implications for the growth problems of the less developed countries follow. I hesitate to formulate them explicitly since the data and the stock of knowledge on which the observations rest are limited. But at least one implication is sufficiently intriguing, and seems to be illuminating of many recent events in the field, to warrant a brief note. It is that a substantial economic advance in the less developed countries may require modifications in the available stock of material technology, and probably even greater innovations in political and social structure. It will not be a matter of merely borrowing existing tools, material and social; or of directly applying past patterns of growth, merely allowing for the difference in parameters.

The innovational requirements are likely to be particularly great in the social and political structures. The rather violent changes in these structures that occurred in those countries that have forged ahead with highly forced industrialization under Communist auspices, the pioneer entry going back over forty years (beginning with the first Five-Year Plan in the *USSR*), are conspicuous illustrations of the kind of social invention and innovation that may be involved. And the variants even of Communist organization, let alone those of democracy and of non-Communist authoritarianism, are familiar. It would be an oversimplification to argue that these innovations in the social and political structures were made primarily in response to the strain between economic backwardness and the potential of modern economic growth; or to claim that they were inexor-

able effects of antecedent history. But to whatever the struggle for political and social organization is a response, once it has been resolved, the results shape significantly the conditions under which economic growth can occur. It seems highly probable that a long period of experimentation and struggle toward a viable political framework compatible with adequate economic growth lies ahead for most less developed countries of today; and this process will become more intensive and acute as the *perceived* gap widens between what has been attained and what is attainable with modern economic growth. While an economist can argue that some aspects of growth must be present because they are indispensable components (i.e., industrialization, large scale of production, etc.), even their parameters are bound to be variable; and many specific characteristics will be so dependent upon the outcome of the social and political innovations that extrapolation from the past is extremely hazardous.

V. Concluding Comments

The aim of the discussion was to sketch the major characteristics of modern economic growth, and to note some of the implications that the empirical study of economic growth of nations suggests. This study goes back to the beginning of our discipline, as indicated by the title of Adam Smith's founding treatise, *Wealth of Nations*, which could as well have been called the Economic Growth of Nations. But the quantitative base and interest in economic growth have widened greatly in the last three to four decades, and the accumulated results of past study of economic history and of past economic analysis could be combined with the richer stock of quantitative data to advance the empirical study of the process. The sketch above draws upon the results of many and widely varied studies in many countries, most of them economically developed; and the discussion reflects a wide collective effort, however individual some of my interpretations may be.

The most distinctive feature of modern economic growth is the combination of a high rate of aggregate growth with disrupting effects and new "problems." The high rate of growth is sustained by the interplay between mass applications of technological innovations based on additions to the stock of knowledge and further additions to that stock. The disrupting effects are those imposed by the rapid rate of change in economic and social structure. The problems are the unexpected and unforeseeable results of the spread of innovations (with emphasis on the new and unknown indicated by that term). Added to this is the range of problems raised by the slow spread of economic growth to the less developed countries, all of which have a long history, separate and relatively isolated from the areas within which modern economic growth originated. Thus, concurrent with the remarkable positive achievements of modern economic growth are unexpected negative results even within the developed countries; while the less developed countries are struggling in the attempt to use the large potential of modern technology in order to assume an adequate role in the one and interdependent world (from which they cannot withdraw even if they wished to do so).

We have stressed the problem aspects of modern economic growth because they indicate the directions of further research in the field. These aspects, the "surprises" and the implicit explanatory "puzzles," are problems not only in the sense of departures from the desirable (that may call for policy amelioration) but also in the sense that our quantitative data and particularly our analytical hypotheses do not provide us with a full view and explanation. As already noted, the conventional measures of national product and its components do not reflect many costs of ad-

justment in the economic and social structures to the channeling of major technological innovations; and, indeed, also omit some positive returns. The earlier theory that underlies these measures defined the productive factors in a relatively narrow way, and left the rise in productivity as an unexplained gap, as a measure of our ignorance. This shortcoming of the theory in confrontation with the new findings, has led to a lively discussion in the field in recent years, and to attempts to expand the national accounting framework to encompass the so far hidden but clearly important costs, for example, in education as capital investment, in the shift to urban life, or in the pollution and other negative results of mass production. These efforts will also uncover some so far unmeasured positive returns—in the way of greater health and longevity, greater mobility, more leisure, less income inequality, and the like. The related efforts to include the additions to knowledge in the framework of economic analysis, the greater attention to the uses of time and to the household as the focus of economic decision not only on consumption but also on investment, are steps in the same direction. It seems fairly clear that a number of analytical and measurement problems remain in the theory and in the evaluation of economic growth in the developed countries themselves; and that one may look forward to major changes in some aspects of the analysis, in national economic accounting, and in the stock of empirical findings, which will occupy economists in the developed countries in the years ahead.

For the less developed countries the tasks of economic research are somewhat different: the great need is for a wider supply of tested data, which means essentially data that have been scrutinized in the process of use for economic analysis. As already noted, the stock of data and of economic analysis is far poorer for these countries than that for the developed countries—a parallel to the smaller relative supply of material capital. Yet in recent years there has been rapid accumulation of data for many less developed areas, other than those that, like Mainland China, view data as information useful to their enemies (external or internal) and are therefore either not revealed by government or possibly not even collected. The lag has been in the analysis of these data by economists and other social science scholars, because of the scarcity of such scholars who cannot be spared for research within the less developed countries themselves and because of the natural preoccupation of economists in the developed countries with the problems of their own countries. One may hope, but with limited expectations, that the task of refining analysis and measurement in the developed countries will not be pursued to the exclusion or neglect of badly needed studies of the less developed countries, studies that would deal with the quantitative bases and institutional conditions of their performance, in addition to those concentrating on what appear to be their major bottlenecks and the seemingly optimal policy prescriptions.

The Economics of the Network-Affiliate Relationship in the Television Broadcasting Industry

By Stanley M. Besen and Ronald Soligo*

Under various acts of Congress, the Federal Communications Commission is empowered to regulate the television broadcasting industry in the public interest.[1] Among the Commission's objectives have been the promotion of program diversity, the encouragement of local programming, and the maintenance of widespread ownership of broadcasting facilities.[2] In order to further these objectives, the FCC has limited the number of local broadcasting stations which can be owned by any one group of individuals or corporations, including networks, and forbidden network affiliates from entering into agreements to accept specific amounts of network programming during specified hours. In addition, the FCC has recently established a ceiling on the number of hours during prime time which a local station can "clear" for network programs.[3] In this paper we have formulated a model of the network-affiliate relationship which allows us to examine the effects of each of these regulations and to examine the extent to which FCC objectives are consistent with one another.

* Associate professors of economics, Rice University. We wish to acknowledge the helpful comments of Marian Krzyzaniak, Harold Barnett, and Edward Greenberg on earlier drafts.

[3] In the jargon of the industry, to clear time for the network means to accept network programs; i.e., to keep the time slot clear of other programs.

I. The Network-Affiliate Contract

The specific details of the typical affiliation agreement have been documented by John Peterman and by Harlan Blake and Jack Blum. For our purposes, the important features of these contracts are the methods by which advertising revenue is shared by the network and affiliate. The standard agreement separates broadcasting time into two categories: announcement time and program time. The announcement time is the brief interval between programs in which the station identifies itself and sells spot commercials. Local stations usually keep all revenue from these sales. Program time is the time during which program material is being broadcast. The networks sell segments of this time for commercial messages. The price which the network charges for this time is determined separately for each station carrying the network program and the revenue which the network collects from these sales is shared with the local affiliates except for a certain specified amount of cleared time for which the network retains all of the revenue.

The important dimensions of the affiliation agreement are i) the length of announcement time allowed by the network, ii) the proportion of program time revenue returned to affiliates, and iii) the number of hours for which all program time revenue is kept by the network. (Hereafter this is referred to as uncompensated time.)

II. A Simple Model of Affiliate Behavior

In order to understand the basic features of the process by which the terms of the affiliation agreement, the number of affiliates, and the number of hours cleared are determined, we develop a model of affiliate behavior. Initially, we consider a highly simplified version of the model. As we proceed, we relax a number of its restrictive assumptions. In the simplified model we assume:

1. The proportion of program time revenue, p, returned to a station is assumed to be the same for all programs cleared regardless of the time during the day at which it is cleared.
2. The amount of announcement time is fixed and not subject to change by the network or station.
3. There is no uncompensated time.
4. There are no constraints on the value or number of hours which the local station must or must not clear for network programming. The affiliates can choose to clear anything from zero to 100 percent of its time for the networks.
5. All network programming costs are fixed. The marginal cost of supplying an additional hour of existing network programming to an affiliate or potential affiliate is zero.
6. In making an agreement, both the station and the network act as if the behavior of other stations and networks is not affected by the nature of the agreement reached.

Since different hours of the day or week will have different values and hence one hour is qualitatively not the same as another, we take as the decision variable for a particular station the value of the time cleared for network programming. The total value of hours cleared is equal to the sum of the amounts which each hour cleared will yield in program time advertising revenue. This in turn is affected by the size of the market (population, number of TV sets, number of TV stations, time of day, what other stations are broadcasting and so on).

The value of hours cleared by a station is, given all of the above assumptions and parameters, a function of p, the proportion of the program time revenue which is returned to the station. Given the value of announcement time if it adjoins a local program, its value if it adjoins a network program, the value of program time for network and nonnetwork programs, and the cost of nonnetwork programs, it is possible to array time periods according to the value of p for which it will pay the local station to clear the network program.

If A_i^L represents the value of advertising during program time for a nonnetwork program during the ith hour of the broadcasting day, C_i the cost of the program, and S_i^L the value of advertising during the announcement time adjoining the program, the return to the local station from a nonnetwork program during that time period is

$$V_i^L = A_i^L + S_i^L - C_i \tag{1}$$

If A_i^N is the value of program time for a network program during the ith hour and S_i^N, the value of the announcement time adjoining the network program, the return to the affiliate from clearing the network program is equal to $pA_i^N+S_i^N$. In deciding whether or not to clear the ith hour for a network program, the affiliate compares these two returns. If $pA_i^N+S_i^N>V_i^L$ the station accepts the network program. Otherwise it does not.

For each hour of broadcasting time the affiliate can calculate the value of p for which it would be indifferent between network and nonnetwork programming. If we denote this p by $\hat{p}_i$ we have, for each i

$$\hat{p}_i A_i^N + S_i^N = V_i^L \tag{2}$$

or

$$\hat{p}_i A_i^N = V_i^L - S_i^N \tag{3}$$

If we array program hours according to $\hat{p}_i$, we can construct a schedule which indicates, for each level of p, the value of hours which the affiliate would be willing to clear for network programming.[4] The higher the p, the greater will be both the number and the value of hours cleared for network programs.[5]

In Figure 1, we have plotted such a "supply" curve for a representative station as BC. The horizontal axis measures the total amount advertisers pay for program time commercial messages during the hours cleared for network programs. The point A^* represents the acceptance of all network programs. We have drawn the curve so that it has a negative intercept. In general, we expect that there are some hours for which $S_i^N > V_i^L$, in which case the local affiliate would even be willing to pay the network for the right to clear network programs, i.e., the value of $\hat{p}$ would be negative. This situation arises because the value of announcement time is greater if the time is adjacent to a network program than if it adjoins a locally originated program and because by clearing a network program a station avoids the cost of program origination.[6]

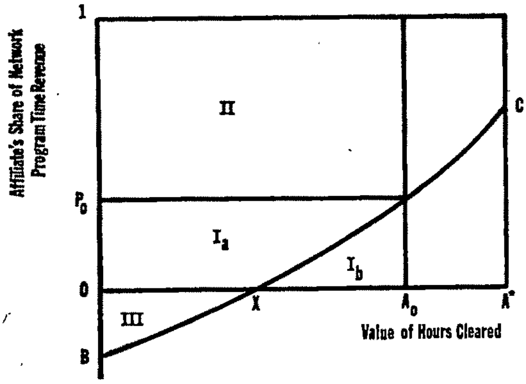

FIGURE 1

If the level of p set by the network is p_O, the station will clear hours worth A_O. The revenue which it collects from the network as its share of the network program time revenues is given by the rectangular area $I_a + I_b$. The network's revenue from the programs cleared on this station is area II. The net profit to the station from network affiliation, i.e., revenues over and above profits, if any, which could be earned from locally originated programs for these hours, is given by the area $I_a + III$.[7] This is the value of network affiliation to the local station. It is a quasi rent which accrues to the local affiliate so long as the network does not engage in price discrimination by establishing a different p for each hour of time cleared.

What value of p will be set by the network for the affiliate depicted in Figure 1? As the network raises p, the value of hours

[4] Note also that we are assuming that, for any i, V_i^L is independent of the amount of time cleared for network programming. This assumption is undoubtedly not strictly correct.

[5] One alternative available to a station is to originate local programs. Another is the purchase of a program from a company specializing in the production of programs. In this case, too, the local station retains all revenue from program advertising. Still another alternative is the so-called barter arrangement. Here, an advertiser supplies a program free of charge to a local station and the latter is permitted to sell some program advertising time from which it can retain all revenues. Even if less advertising revenue accrues to the local station under this arrangement because the supplier of the program does not pay for his advertising time, it may still be the best alternative to a network program since the station avoids the cost of originating or purchasing a program. Of course, it is the return from the best alternative which will be compared to the gains from accepting network programming.

[6] There may be markets where local programming is very profitable, relative to network programs. In this case, the local station will not be willing to clear any network programs without a positive p. The supply curve for this station would have a positive intercept. These cases are, however, rare. There are no stations which do not affiliate with a network if they can.

[7] Recall that the supply curve represents the opportunity cost of program time to the affiliate. Hours to the left of X have negative opportunity cost; i.e., the affiliate would pay for network programming if necessary.

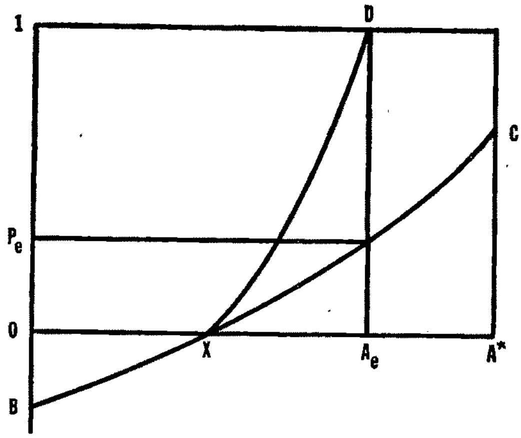

FIGURE 2

cleared by the affiliate increases. The profits that the network earns on the newly cleared units is at least partially offset, however, by the decline in revenue on previously cleared units. In other words, since a lower value of $1-p$ must be accepted on all previously cleared units, the return from an additional unit cleared is less than $1-p$ for that unit. The network will, therefore, employ the curve marginal to the supply curve, XD in Figure 2, in determining the value of p for which its profits are a maximum.[8] By assumption, the marginal cost of supplying a program to an additional station is zero.[9] Therefore, profits are maximized when the curve marginal to the supply curve intersects the horizontal line for $p=1$. Given this, the profit maximizing value of p can be determined.[10] In Figure 2 this is p_e. In equilibrium, the affiliated station is indifferent between clearing the last hour of network programming, A_e, and not doing so. Note that the price charged by the network, $(1-p)$ times advertising revenue, exceeds the cost (zero by assumption) of supplying an additional hour of programming to the affiliate.

III. Price Discrimination by Network

Suppose that the network has considerable market power since the number of stations exceeds the number of networks in a given market and some stations will not be able to obtain an affiliation. In principle, the network should be able to extract the entire increment to the profits of an affiliate generated by network affiliation. One way to do this would be to charge different prices for each program cleared.[11] Another way of accomplishing the same objective is not to compensate the affiliate for all programs cleared and to require in the contract of affiliation that the affiliate clear some minimum number of hours. We consider these, in turn.

Uncompensated Time

The uncompensated time constraint can be described as follows: If the value of advertising during an hour of prime time on a network program is A_P^N and if the constraint is H hours,[12] then the affiliate does not share in program time advertising revenue on the first HA_P^N dollars worth of network time that it clears.

Consider an affiliate which was clearing time periods of value greater than HA_P^N in the absence of the constraint. When a constraint of that amount is imposed, the affiliate will clearly wish to satisfy it with the smallest loss of profits. Given p, it will never clear hours not previously cleared

[8] The curve XD does not extend below the horizontal axis because the network will have programs of value OX cleared even if $p=0$. If the network were permitted to make p negative, i.e., to charge the affiliate for a cleared program, the curve marginal to the supply curve would begin at B.

[9] This departs from reality in that the network typically pays the AT&T interconnection charge.

[10] For example, if the supply curve were a straight line, p would equal 1/2.

[11] Notice that this would require a negative p for programs to the left of X. We will return to this point shortly.

[12] The constraint is specified, in the affiliation contract, in terms of prime time hours or equivalents thereof but is, in effect, a claim to an amount of revenue rather than to a number of hours.

(when there was no constraint) in order to satisfy the constraint. In Figure 3, hours previously cleared have an aggregate value of A_O for $p=p_O$. The constraint is shown as $\bar{A}$. If, after the imposition of the constraint, the affiliate continues to clear time periods of value greater than $\bar{A}$ it will continue to clear A_O since eliminating a single program does not affect the constraint and contributes a positive amount, $(pA^N+S^N-V^L)$, to profits. But if area I is greater than area II, the affiliate would be better off if it reduced the value of hours cleared to OX. This is a preferred position because the gain from clearing hours between $\bar{A}$ and A_O is less than the foregone income on hours between X and $\bar{A}$. The affiliate would continue to clear hours up to X, however, since all hours to the left of X have the characteristic that S^N exceeds V^L and would be cleared even if p were negative.

What effect does the possibility of employing an uncompensated time constraint have on the policy pursued by a network with respect to a particular station? It is easy to see that the optimal policy for the network is to set p sufficiently high so that all network programs are cleared and to adjust the constraint so that the affiliate's profits from network affiliation are almost

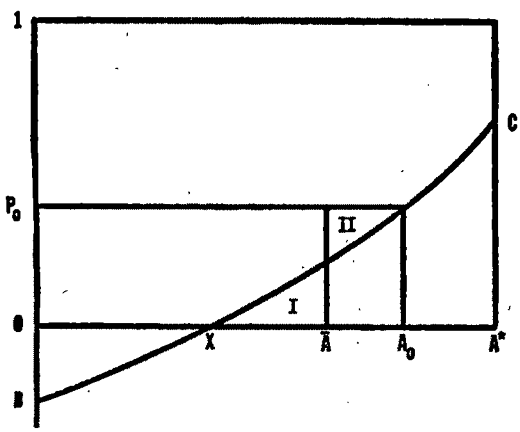

FIGURE 3

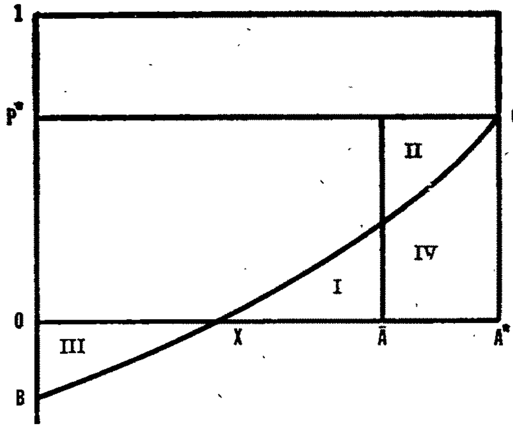

FIGURE 4

eliminated. This is demonstrated in Figure 4, where A^* represents the acceptance of all network programs, the sharing ratio is set at p^* and the constraint at $\bar{A}$ so that area I is equal to area II. If the constraint were any larger, the affiliate would be induced to reduce the number of hours cleared to OX. Notice that in this case the affiliate would continue to earn profits from network affiliation equal to area III.

If the network acted as a perfect price discriminator and set $p=\hat{p}$ for each hour to the right of X, profits accruing to the affiliate on these hours would be equal to areas I and IV. Since these profits are equal to what the station would earn if it were an independent station, profits from network affiliation on hours to the right of X would be zero. The uncompensated time constraint thus appears as a relatively simple, yet sophisticated, device for practicing price discrimination among hours. Instead of setting prices on each program individually the network simply establishes a sharing ratio sufficiently high so that all network programs are cleared and then adjusts the constraint so as to eliminate almost all of the profits from affiliation and, at the same time, maximizes the profits of the network.

The above arrangement with a high sharing ratio and a large amount of un-

compensated time is very similar to the incentive contract initiated by CBS in 1961 and subsequently overturned by the FCC in 1962. The CBS contract called for affiliates to receive 10 percent of the revenue from the first three-fifths of the programs that CBS asked them to clear and 60 percent of the revenue from all additional programs cleared. This sharing ratio contrasts sharply with the 30 percent which prevailed both before and since the imposition of the incentive contract. The FCC overturned the contract on the grounds that it unduly restricted the ability of nonnetwork program sources to obtain clearances on CBS affiliates.[13,14]

The overturning of the CBS incentive contract raises the question of how the terms of network-affiliate contracts are affected by it. From the comments made at the time by the FCC, we deduce that the constraint imposed is in terms of a maximum sharing ratio permitted,[15] say p_{max}. With such a restriction, the network would set the constraint so that the affiliate is indifferent between clearing the number of hours cleared at p_{max} and OX, the minimum amount that affiliates would always want to clear. The situation is depicted in Figure 5 where area I is equal to area II. The effect of the constraint, and the principal one intended by FCC policy, is to

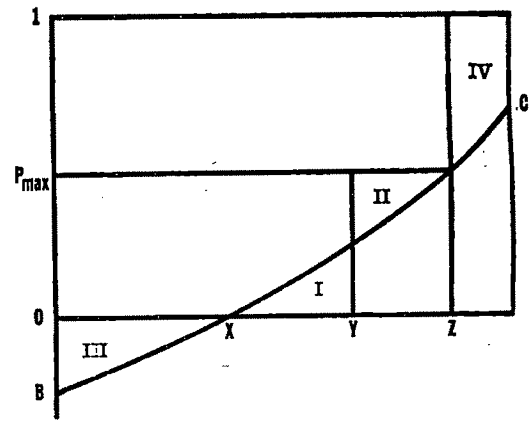

FIGURE 5

reduce the number of network hours which an affiliate will accept. The quasi rents earned by the affiliate as a result of network affiliation are still restricted to area III but the profits earned by the network are much reduced (by area IV) from those obtained where there is no restriction on p.

Option Time

A network which has the power to practice price discrimination need not settle for almost all of the quasi rent it generates for its affiliates. Under certain circumstances it may also be able to extract the quasi rent earned on hours cleared to the left of OX. The device employed is called option time[16] whereby the affiliate must clear some minimum number of hours for network programs.

Consider the situation depicted in Figure 6 which partly reproduces Figure 4. If the value of uncompensated time were increased beyond $\bar{A}$, say to $\hat{A}$, the affiliate would clear only OX hours, since with a constraint equal to $\bar{A}$ the station was indifferent between clearing OA^* hours and OX hours. The change in the constraint

[13] See *Wall Street Journal*, Apr. 13, 1962, p. 4, and June 1, 1962, p. 14.

[14] In some instances, there has been a more direct form of price discrimination by hours. For example, in 1956, the contract of WNBF affiliate in Binghamton, New York, called for a 25 percent sharing ratio on the first 20 hours cleared, a 35 percent ratio on the next 10 hours, and 40 percent on all additional hours. At the same time the CBS affiliate in Youngstown, Ohio, WKBN, received 10 percent on the first 5 hours cleared, 20 percent on the next 5, and 30 percent on all other hours. However, such sliding scale arrangements are apparently not common. On the terms of contracts see U.S. Congress, Hearings: *Monopoly Problems in Regulated Industries, Part 2, Television*.

[15] This is the aspect of the contract that limits the ability of nonnetwork program sources to compete with networks for program time.

[16] Option time was forbidden to be included in the contract of affiliation in 1963. Yet, some observers of the industry believe, local stations are often "forced" to accept programs they would otherwise not clear. The threat used against them is the withdrawal of affiliation.

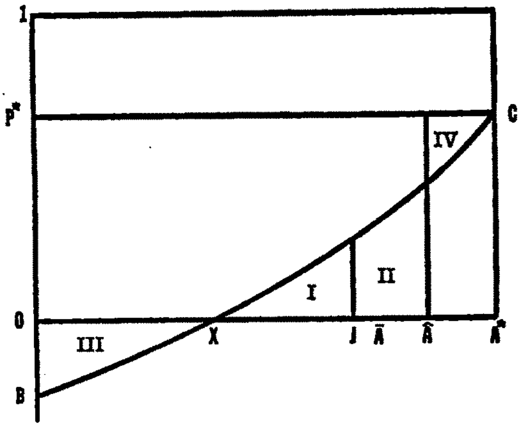

FIGURE 6

induces a shift to OX. But suppose that the contract of affiliation requires that hours of value at least OJ be cleared. Then the station must decide whether it will clear OJ hours, and perhaps some larger number of hours, or refuse the opportunity to affiliate. Which course it will choose depends on the relationship between areas III and I in Figure 6. If the network sets OJ so that these areas are equal, then at least OJ hours will be cleared. The loss on the hours between OX and OJ, area I, is just compensated for by the quasi rents earned on the first OX hours, area III. In fact, the station then considers, as a marginal decision, whether to clear some larger number of hours. If area IV is greater than area II, it will clear all network programming since the loss on hours between J and $\hat{A}$ is more than compensated for by the gain on hours between $\hat{A}$ and A^*. If $\hat{A}$ is set so that areas II and IV are equal in addition to setting the option time OJ so that areas I and III are equal, the network will be able to extract all of the quasi rents that it generates.

To summarize: The use of uncompensated time is a device for practicing price discrimination which can eliminate almost all of the quasi rents which would otherwise be received by a network affiliate as a result of affiliation. Combined with option time, or some "unofficial" requirement that some minimum number of hours be cleared, all of the quasi rents can, in principle at least, be eliminated. Placing restriction on the maximum sharing ratio results in a decline in network profits with no corresponding gain in affiliate profits. The bar against option time, if it is effective, may result in some quasi rents being retained by the affiliate.

IV. Price Discrimination by Stations

To this point we have considered situations in which the networks have considerable market power vis-à-vis potential affiliates. This presumably occurs in markets in which there are very many stations, each vying for the right to be an affiliate. In other markets, however, the situation is reversed. A small number (one or two) stations exist and each of the networks would wish to have the station as its affiliate. Here, competition among the networks should completely eliminate any profits that networks obtain from having an additional affiliate. Rent accrues to the station from being an affiliate as well as from the fact that it is one of a small number of stations in the market. If, from the point of view of the station, one of the network affiliations is more desirable than the others in the sense that advertising revenues from that network's programs are larger, then that network can obtain the portion of revenue which results from its superior programming. This is the portion of the rents which results from the differential productivity of the networks.

V. Affiliate Profits and Market Structure

As we have pointed out above, our model has some implications for the profitability of network affiliates in markets in which there are more stations than networks. In the absence of any FCC restrictions, some combination of sharing ratio, uncompensated time, and option time should succeed in eliminating all quasi rents which would

otherwise accrue to a station from its affiliation with a network. In such markets, network stations should be no more profitable than are independents. If, however, option time is not permitted, and the restriction is effective, a portion of the quasi rents will continue to accrue to affiliates.

There is some empirical evidence on this point. Edward Greenberg has shown that, in markets with four or more stations, network affiliates are more profitable than are independents when other determinants of profitability are allowed for. This indicates that, even in markets in which competition among stations for the right to a network affiliation might be expected to lead to the extraction by networks of all profits from affiliation this does not in fact occur.[17] The implication of this is that either the FCC prohibition of option time is effective or that network pricing policies are not such as to fully eliminate the additional revenue that network affiliation produces.[18] Further, it follows, a fortiori, that in markets with less than four stations, where the bargaining power of the network is weaker, it is even more likely that local stations are able to capture at least a portion of the incremental revenues which results from affiliation.

VI. The Prime Time Access Rule

The FCC has recently enacted a rule which restricts the number of prime time hours which an affiliate can clear to a network.[19] Assuming that the affected affiliates do not now satisfy this constraint, as is likely to be the case, what is its effect? We assume that the situation which the Prime Time Access Rule will affect is that depicted in Figure 5 where there is both an upper bound to the sharing ratio and the absence of option time. In Figure 5, the value of uncompensated time is set at OY hours. If the program omitted by the network as a result of the Prime Time Access Rule lies to the left of OY, the impact of the rule will be to raise the value of uncompensated time. The affiliate's loss on programming to the left of Y caused by the existence of uncompensated time is now reduced with the elimination of one program. The network can now increase uncompensated time in order to, once again, equalize areas I and II. If, on the other hand, the program omitted lies to the right of OY, the impact will be to reduce the value of uncompensated time. To predict the precise impact of the rule would, therefore, require detailed knowledge of the value to the affiliates of the programs to be omitted.[20] In either case, network profits will be reduced.[21,22]

[17] Harvey Levin also found that network affiliation is significant as a determinant of the value of a station even when the effect of other factors is allowed for.

[18] There is one further possibility: Greenberg's results may reflect the fact that UHF stations are less profitable than VHF stations, and that network affiliates are largely the latter. A UHF-VHF variable was not significant in Greenberg's regressions but this may be explained by the multicollinearity between this variable and the network affiliation variable.

[19] The rule, which would apply only to affiliates located in the 50 largest markets, would prohibit stations from carrying more than 3 hours of network programming other than news between 7 and 11 P.M. Because each offers a half hour early evening news program the practical effect would be to reduce network programs by one-half hour each night. Networks would be forbidden from extending news programming. See *Wall Street Journal*, Apr. 15, 1970, p. 2 and May 4, 1970, p. 10.

[20] The omitted program is most likely to lie to the right of OY. Since the network is assumed to vary the uncompensated time constraint so as to extract all quasi rents from network programs, the contribution to the network's profits from any one program is equal to the difference between the amount of program time revenue (net of costs) paid to affiliates and the amount which must be paid in order to induce the affiliate to carry the program. In the case where all prime time hours produce the same program time revenue (net of costs), the decrease in the network's profits due to the Prime Time Access Rule is minimized for a given p if the network eliminates that prime time program having the largest $\hat{p}$. Affiliation contracts currently call for about 30 hours of uncompensated time per month while prime time programming amounts to approximately 120 hours per month. Since only 15 hours of network programming must be eliminated, prime time hours having the largest $\hat{p}$ will lie to the right of OY. This conclusion may not hold in the case when prime time hours do not yield equal revenue.

[21] A network spokesman has estimated that a loss of

VII. The Group Ownership Rule and the Fourth Network

One of the perplexing aspects of behavior in the television broadcasting industry is the fact that very large profits are earned by affiliated television stations, yet the formation of a fourth commercial network has not taken place.[23] This has apparently resulted in very small profits for those stations unable to obtain an affiliation, and, in some cases, the failure to obtain an affiliation has forced stations out of business.

The formation of a network involves very substantial costs which are independent of the number of affiliates. In addition, there are relatively low costs of supplying an additional station with programming.[24] According to a well-known proposition in welfare economics, the undertaking of any indivisible activity is justified if a perfectly discriminating monopoly could profit from doing so. And that would seem to be the appropriate test for the introduction of a fourth network. But the results of our analysis are that networks will be unable to extract all of the extra benefits that they generate in markets in which the number of stations is smaller than the number of networks. And, further, while it would seem possible for networks to extract all quasi rents which they might generate in other markets, they apparently fail to do so either because they are not very efficient price discriminators, because of the ban on option time, or both. As a result, some of the benefits generated by the formation of a network accrue not to the network but to its affiliated stations. This fact may partly explain why a fourth network is not formed even though it may be economically justified.

One way to allow networks to appropriate all of the benefits which they generate, the outright ownership of affiliates by the network, is precluded by the Group Ownership Rule which restricts the number of stations that a network can own.

In addition to restricting the degree to which networks can appropriate the rents which they generate, some FCC regulations such as the maximum permitted sharing ratio and the Prime Time Rule simply reduce network profits without increasing the profits of affiliated stations. These regulations also reduce the likelihood that a fourth network will develop.[25]

It may seem paradoxical at first that permitting networks to receive larger profits can enhance the success of local stations. But the paradox can be resolved when one realizes that most, if not all, of the marginal television stations have no network affiliation, and that a network affiliation, even on terms which are very favorable to the network, may be better than no affiliation at all.

VIII. Conclusion

This paper has provided a model of the economic relationship between television

one-half hour of prime time could cost each network \$6–14 million per year in gross profits. See *Wall Street Journal*, Apr. 15, 1970, p. 2.

The FCC limitation of the proposed rule to the 50 largest markets is apparently based on the assumption the networks will continue to furnish their affiliates in other markets with network programming throughout prime time. Apparently some of the smaller stations fear that they will not be able to obtain network programming through prime time, *Wall Street Journal*, May 8, 1970, p. 4. See also the *Wall Street Journal* editorial, May 13, 1970, which expresses a similar fear.

[22] It is useful to point out that there exists a relationship between our analysis of the ban on option time, the prime time rule, and the ceiling to the sharing ratio, and the literature on the behavior of the regulated firm. See, for example, Harvey Averch and Leland Johnson. Unlike the Averch-Johnson model, where the constraint imposed on the regulated firm is in terms of the maximum rate of return that it is permitted to earn, in our model the profits of the networks are not directly regulated and the restrictions take other forms.

[23] There have been a number of abortive attempts to form such a network.

[24] The principal incremental cost is the AT&T interconnection charge.

[25] Another barrier to entry of a fourth network which has been alleged to be important is the structure of AT&T interconnection charges. On this point see, for example, Joel Dirlam and Alfred Kahn.

networks and their affiliates. The model was employed to examine the manner in which advertising revenues are shared. We were able to demonstrate that the use of uncompensated time and of option time both contribute to the ability of television networks to extract the quasi rents which would otherwise accrue to local stations as a result of their network affiliation. We also analyzed the impact of the ban on option time, the restriction on the maximum permissible sharing ratio, and the new Prime Time Access Rule. An important policy conclusion is that these rules in addition to the limitation on station ownership imposed by the Group Ownership Rule may be important barriers to the development of a fourth network.

On The Theory of Optimal Investment, Dividends, and Growth in the Firm

By CLEMENT G. KROUSE*

The consideration of time-optimal programs for corporate investments, dividends, and growth is a relatively new area of microeconomics. Although the specification of a maximand appropriate for such models has been well studied,[1] little systematic attention has been given to a model with suitable dynamic structure and, subsequently, to the intertemporal dependencies which relate the firm's value and earnings to decisions on financing and investments. It is the purpose of this paper to consider this second problem, particularly with regard to generalizing the conditions under which the theory of valuation can be used to determine the unlevered firm's optimal financing and investment decisions.

Previous formulations of dividend, investment, and growth programs for the firm have been restrictive in giving consideration only to one of two polar cases. One approach has identified dividend policy on a one-to-one basis with investment policy and thus confounded the two,[2] while the other has abstracted from the interdependencies between investment and financing decisions.[3] The difficulties associated with the first kind of abstraction have been fully outlined by Miller-Modigliani nearly a decade ago and need not be reviewed. The difficulties inherent in the second abstraction, although not considered by the literature in this context, are not less, for they set aside a fundamental proposition of modern capital analysis requiring that both (the firm's) production and exchange opportunities be jointly considered to yield a time optimal path for (shareholder) consumption claims.[4] To this end, this study explicitly and simultaneously treats the shareholder valuation functional and the firm's intertemporal earnings-possibility equation to make fully clear the conditions under which investment and financing opportunities, while distinct, interact to determine optima which involve unique and nonunique specifications of these two.

A further restrictive characteristic of prior corporate investment and financing studies is their a priori assumption of stationary-growth conditions. Particularly, they consider only the special equilibrium structure of corporate events where the economic state of the firm is identical in every period except by a constant scale factor, and all its decisions and exogenous variables (for example, discount rates) are required to be constant through time. Concomitantly, they limit the models to comparative dynamics, which is not useful for the analysis of the firm's decision rules or states as exogenous variables change over time, but only appropriate for the comparison of firms with different, time-constant values of these variables. While there

[1] Notably by Jack Hirshleifer and Miller-Modigliani.

[2] See Gordon.

[3] See Miller-Modigliani.

[4] With a specified level of operations it is customary to show that the firm's financing decisions leave its total market value unchanged. More precisely, it is necessary to indicate, as herein, the conditions under which financing decisions do not affect the wealth position of initial shareholders. On this point, see Hirsheifer.

are differences in their developments, the models of James Walter, Myron Gordon, Merton Miller-Franco Modigliani, and John Lintner (1967) are typical of the stationary growth forms.[5]

The perspective of the firm taken herein is that of a dynamic, discrete-time activity. The firm is not a priori required to maintain constant growth rates in dividends or earnings, but is fully free to make financing and investment decisions consistent with optimizing initial shareholder wealth. Since our objective is to address specifically the optimal capital accumulation and financing problems of the corporation, production technology and product-factor demand functions are simply subsumed in the specification of an earnings-possibility function. Earnings are defined as income net of economic depreciation and, on the basis of this definition, a first-order difference equation is developed to relate their level at any point in time to prior levels and the size and financing source of capital budgets.

With regard to the objective function, the neoclassical theory of optimal capital accumulation is employed which implies using an objective maximizing the utility of a stream of consumption. Further, based on the proof of Hirshleifer that the maximization of the firm's present value is the only criterion fully in agreement with the external consumption stream objective, the frequently cited maximization of the average internal rate of return on invested equity, geometric rate of earnings growth, etc. are disregarded and the focus placed singularly on extremizing the discounted stream of dividends paid (over an infinite horizon) to the firm's "initial" shareholders.

[5] Particularly, the M-M "convenient case of constant growth rates" and the Lintner certainty model. Gordon and Walter, it should be noted, consider only the all retained-earnings financing assumption while the other studies also admit external equity financing.

Necessary and sufficient conditions for extremal earnings and dividend time sequences, along with a program of time-optimal retained earnings and external equity decisions, are developed based on this model. In important ways these extremal conditions extend to greater generality the commonly used marginal earnings efficiencies of the various financing sources and the frequently cited Miller-Modigliani proposition concerning the null effects of the financing mode on the firm's market value. Finally, the specific effects of technical progress and market discount rates on the optimal size of the capital sources in each period are developed.

I. The Model

While there is an increasing volume of theoretical literature examining the investment, financing, and growth of the firm, the failure to be fully explicit about specializing assumptions and to clearly set forth definitions of economic variables has unnecessarily led to misinterpretations of these analyses, particularly with regard to the generality of their conclusions. To this end this section sets out in detail the variables and important analytical components of the current model, in part so that the reader can be clear about the proper limits of its implications and in part to show the fundamental respects in which it generalizes prior studies.

First, define the usual variables of the firm.

$D(t)$ = *total* dollar amount of dividends paid at time t.

$D_T(t)$ = portion (in dollars) of time t dividends paid to shareholders of record at time T.

$k(t)$ = time t market discount *factor*, discounting back to time zero,

$$k(t) = \prod_{\tau=0}^{t} \{1/[1 + r(\tau)]\}$$

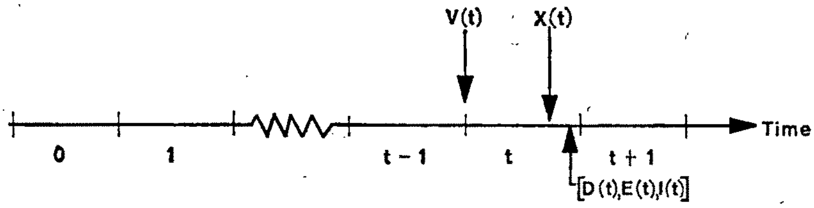

FIGURE 1. THE ECONOMIC PROCESS

where $r(\tau)$ is the one period opportunity rate available to the firm's shareholders.

$X(t)$ = time t net earnings of the firm (net of economic depreciation).[6]

$I(t)$ = transaction costless *internal* equity decision variable in period t—retained earnings for $0 \leq I(t) \leq X(t)$, with a preemptive ("rights") offering when $I(t) > X(t)$.

$E(t)$ = *external* equity decision in period t having associated transaction (brokerage) costs; expressed as the total dollar amount of the acquisition, $E(t) > 0$, or retirement, $E(t) < 0$, *including* transaction costs.

$\delta(E(t), t)$ = the ratio of the time t market price of an equity share to its external issue price: $\delta(t)$ for notational convenience. $\delta(t) < 1$ implies issuance of shares at a premium to market price, and conversely for $\delta(1) > 1$. Some expectations/information asymmetry among potential shareholders is held to account when $\delta(t) \neq 1$.

$V(t)$ = value of the corporation at the beginning of period t to shareholders of record at *that* time.

Taxes are everywhere neglected for convenience. The timing of the decisions and money flows is depicted in Figure 1. For a representative period t the sequence of occurrences is such that, after earnings are realized, all decisions are made at essentially period end. In keeping with convention, the value of the firm is established at the beginning of the period. Thus, new external equity is raised in every period *ex dividends* of that period.

Given these definitions, the value of the corporation at an arbitrary time, t = 0, to shareholders of record at that time, $V(0)$, can be represented by the functional

$$V(0) = \sum_{t=0}^{\infty} D_0(t)k(t) \tag{1}$$

The expression explicitly allows for the future issue of new external equity shares. This particular form, however, is of limited use since $D_0(t)$ is not an easily observable state or decision of the firm and it is accordingly convenient to transform the functional. Separating initial from later periods, rewrite equation (1) in the form.

$$V(0) = k(0)D_0(0) + k(0)\sum_{t=1}^{\infty} D_0(t)\hat{k}(t)$$

where $\hat{k}(t)$ now discounts back to the beginning of period 1, not 0.

Since new equity shares are issued at the end of period 0, and hence *ex dividends*, the entire initial-period payout is to the initial shareholders. But, only a pro rata portion of the total dividends paid in later periods will accrue to the shareholders of record at

[6] Precisely, the Hicks net income (No. 2) definition is utilized. See chapter 14.

time t=0. Accordingly, $V(0)$ becomes

$$V(0) = k(0)\left\{D(0) + \left[1 - \frac{\delta(0)E(0)}{V(1)}\right] \cdot \sum_{t=1}^{\infty} D_1(t)\hat{k}(t)\right\}$$

The term $E(0)$ is the total dollar amount of external equity acquired (including transaction costs), which may be at an average share price some premium ratio above market value, $\delta(0)<1$, below market value, $\delta(0)>1$, or at market value, $\delta(0)=1$. The final summation term in this expression is the dividend sequence accruing to shareholders of record in period 1 discounted to that time. This is exactly the value of the corporation in period 1, $V(1)$, so the full expression can be simplified to

$$V(0) = k(0)[D(0) - \delta(0)E(0)] + \sum_{t=1}^{\infty} D_1(t)k(t)$$

By recursively employing this procedure for all future periods and further substituting the identity $D(t) \equiv X(t)-I(t)$, current shareholder value over an infinite horizon is written[7]

$$(2) \quad V(0) = \sum_{t=0}^{\infty} [X(t)-I(t)-\delta(t)E(t)]k(t)$$

The contribution to $V(0)$, and hence to the share price to holders of record at t=0, owing to the firm's decisions in any period can be seen to be positive, zero, or negative as dividends are greater/less than the market value of external equity issued (retired), $X(t)-I(t) \gtrless \delta(t)E(t)$. Particularly, in periods when the per share dividend to *market* price ratio is less than the fractional growth in shares outstanding the contribution will be negative.

Although somewhat different in form, the equation (1) expression for $V(0)$ is fully consistent with the familiar Miller-Modigliani equation (3) "fundamental rule of valuation." Assumptions in the sequel concerning decreasing marginal returns to investment, rates of earnings-technical adjustment, and the time properties of the discount factor, $k(t)$ are such to assure the sum converges. Shareholder wealth as expressed by (2) is to be maximized by the choice of a time sequence of investment funding decisions, I and E, from which, insofar as a retained earnings sequence is determined by I, a given dividend strategy follows.

Turning to the firm's earnings time path, it is required to set forth the relationship between the firm's investment budget and mode of financing at every point in time and its resultant earnings *sequence*. Following directly from the definition of the firm's income as net of economic depreciation, the manner in which earnings "spread out" from given investments can be very simply specified by a change function ϕ and the first-order difference equation

$$(3) \quad \Delta X(t) = A(t)\phi[I(t), E(t)]$$

where t denotes time, and $\Delta X(t)$ is a forward difference:

$$(4) \quad \Delta X(t) = X(t+1) - X(t)$$

The term $A(t)$ represents an index of earnings-technical adjustment, which will be shortly described.

The earnings-possibilities function ϕ sets out the firm's one-period net earnings *change* arising from specific investments.[8]

[7] Since retained earnings has been considered the sole source of equity funds in a predominance of corporate growth models, direct discounting of the firm's *total* dividend stream has become generally (and wrongly) identified as the universally proper valuation criterion. As can be seen from the above developments, this is the case *only* for the firm not employing new external equity. In distinction, the form of equation (1) fully compensates the current market value for future dividends that must be diverted to additional equity.

[8] This relation is assembled from demand functions, production functions (or cost functions), and factor prices. It, of course, assumes the optimal allocation of

Particularly, in the case of equation (3) it sets forth the earnings change from t to t+1 owing to the size and financing source of the firm's capital budget at time t. As noted earlier, the new level of earnings, after the one-period increment, is kept intact (unentrenched) throughout all future time via "automatic" reinvestments defined as economic depreciation. Thus, for the firm with zero *net* investments an undegraded new income level is maintained *ad infinitum*. In keeping with conventional assumptions it is further supposed that $\phi(\mathrm{t})$ is continuous through second partial derivatives of $I(\mathrm{t})$ and $E(\mathrm{t})$, has the null property where $\phi[0, 0]=0$, and exhibits decreasing marginal returns to investment in some region.

In the sequel we write

$$(5)\qquad \Delta X(\mathrm{t}) = A(\mathrm{t})\phi(\mathrm{t})$$

where $\phi(\mathrm{t})$ is notational convenience for $\phi[I(\mathrm{t}), E(\mathrm{t})]$.

The index $A(\mathrm{t})$ of the earnings difference equation is a measure of the firm's time t rate of earnings adjustment arising from advancements in the physical technology of production and, more significantly perhaps, from changes in the structure of its factor and/or product markets.[9] Such adjustments are modeled to be autonomous and to occur at a relative rate, $a(\mathrm{t})$, unique to each period:

$$\Delta A(\mathrm{t}) = a(\mathrm{t})A(\mathrm{t})$$

It may be observed that the product $a(\mathrm{t})A(\mathrm{t})$ ties prior earnings-technical affect to the current rate of change. By suitable choice of measure it is further advantageous to require $A(0)=1$, thus

$$(6)\qquad A(\mathrm{t}) = \prod_{\tau=0}^{\mathrm{t}-1}[1 + a(\tau)]$$

Adjustments at time t will be referred to as positive, neutral, or negative depending on whether $a(\mathrm{t})$ is greater than, equal to, or less than zero, respectively.

As a final element of generality, it should be explicitly noted that "negative" retained earnings are permitted to accommodate disinvestment and that negative dividends are permitted to accommodate preemptive ("rights") offerings of shares to existing shareholders. The central feature of such rights issues is their essentially zero transactions costs (so that they are properly entered into the earnings-change function through the transactions-costless internal equity variable).

II. Model Solution

Collecting the equations and definitions introduced to this point, the requirement for a time optimal investment, dividend, and growth program for the firm can be stated as

$$(7\mathrm{a})\qquad \max_{I(\mathrm{t}),\,E(\mathrm{t})} \sum_{\mathrm{t}=0}^{\infty} [X(\mathrm{t})-I(\mathrm{t})-\delta(\mathrm{t})E(\mathrm{t})]k(\mathrm{t})$$

subject to:

$$(7\mathrm{b})\qquad X(\mathrm{t}+1) = X(\mathrm{t}) + A(\mathrm{t})\phi(\mathrm{t})$$

$$(7\mathrm{c})\qquad X(0) \text{ given}$$

$I(\mathrm{t})$ and $E(\mathrm{t})$ are the firm's internal and external equity decision variables and its net earnings level, $X(\mathrm{t})$, is termed a state variable.

Unlike most prior treatments, the completed model of equation (7) states in a clear, choice-theoretic structure the firm's investment and financing problem: the ob-

each marginal dollar of investment, both among existing and potential new markets. Note also that the earnings-possibilities function is written to depend not on a simple investment aggregate in the form $\phi[I(\mathrm{t})+E(\mathrm{t})]$, but more generally by the $\phi[I(\mathrm{t}), E(\mathrm{t})]$ functional relationship. In this way transaction costs associated with acquiring external equity and any relationship between retained earnings and the cost of external funds can be fully reflected.

[9] Changes in product-factor market structure are modeled to affect the firm's earnings only by affecting its investment possibilities—in the sequel it will be seen that the optimal investment rules involve $A(\mathrm{t})$. Product factor-market changes which do not induce investments thus do not give rise to earnings adjustments.

jects of choice are specifically identified; a preference function ordering the choice-objects and resultant economic states is explicit; and, the time-process equation linking the firm's earnings state and decisions is set forth in detail. From this analytical form several distinguishing elements, vis-à-vis prior formulations, can be brought into clearer focus: internal and external equity financing modes are both available; financing decisions are not required to be constant over time, but can be uniquely chosen in each period; the usual constant "internal rate of return" is not imposed on the firm's investment possibilities; neither earnings nor dividend time sequences are a priori required to have any specific time structure; the firm's optimal investment and financing programs are to be jointly and consistently derived (the *total* investment or capital budget results as the net sum of funds from the two capital sources); and, finally, a measure of technical progress in the firm's earnings possibilities is explicitly incorporated, issuance of external equity at above or below market value is admitted, and the market discount rate is not assumed constant but as having a fully flexible time structure.

Looking to the content of equations (7), the firm's problem is to find the *sequences* I^* and E^* that maximize the value to current shareholders. Derivation of such an optimal program can proceed first by adjoining the earnings difference equations to $V(0)$ with a multiplier sequence λ.

$$\overline{V}(0)=\sum_{t=0}^{\infty}\{[X(t)-I(t)-\delta(t)E(t)]k(t) + \lambda(t+1)[X(t)+A(t)\phi(t)-X(t+1)]\} \tag{8}$$

For notational convenience, further define the Hamiltonian sequence over $t=0, 1, 2, \ldots$

$$H(t) \equiv [X(t) - I(t) - \delta(t)E(t)]k(t) + \lambda(t+1)[X(t) + A(t)\phi(t)] \tag{9}$$

The Hamiltonian at any time t is seen to be a sum of that period's discounted change in initial valuation, $V(0)$, and a product term of the auxiliary variable $\lambda(t+1)$, and earnings at time $t-1$. Thus the auxiliary variable has the interpretation of an intertemporally imputed value (shadow price) of an additional dollar of earnings (income) measured in terms of the present value of initial shares.

Finally, change the indices of summation for the $\lambda(t+1)X(t+1)$ term in equation (8) to obtain the notationally simpler expression for $\overline{V}(0)$.

$$\overline{V}(0) = H(0) + \sum_{t=1}^{\infty}[H(t) - \lambda(t)X(t)] \tag{10}$$

In this form solution of the problem can proceed directly by the discrete maximum principle, see Samuel Katz. Choose the convenient multiplier sequence

$$\lambda(t) = \frac{\partial H(t)}{\partial X(t)} = \lambda(t+1) + k(t) \tag{11}$$

which importantly determines the auxiliary variable only as a function of the market discount rates and not as being dependent on any of the firm's decisions or states. Moreover, with the "free end" conditions $\lambda(t)$ becomes zero in the limit as t becomes infinite. Since by (11) $\Delta\lambda(t) = -k(t)$, then $\lambda(0)$ is given as

$$\lambda(0) = \sum_{t=0}^{\infty} k(t) \tag{12}$$

If the market discount rates are always positive, then the $k(t)$ discount factor becomes zero as $t\rightarrow\infty$, and the above summation converges to a finite value—which value simply becomes one over the discount rate itself when that rate is, as in all prior models, considered constant over time. Finally equations (11) and (12) can be combined recursively to yield

$$\lambda(t+1) = \sum_{\tau=t+1}^{\infty} k(\tau) \tag{13}$$

which is a forward sum of discount factors, discounting to $t=0$.

By the maximum principle it is necessary for an optimal financing program that the firm choose $I(t)$ and $E(t)$ to

$$(14) \quad \max H(t) \qquad \text{for all } t = 0, 1, \ldots$$

Important economic implications of this condition become clear if equations (9) and (13) are utilized to write the Hamiltonian as

$$(15) \quad \begin{aligned} H(t) &= [X(t) - I(t) - \delta(t)E(t)]k(t) \\ &\quad + [X(t+1)] \sum_{\tau=t+1}^{\infty} k(\tau) \end{aligned}$$

Thus, it is seen that the maximum principle requires the firm *at each period in time* to maximize a properly weighted sum of a *direct* contribution to market value, $[X(t) - I(t) - \delta(t)E(t)]$, and an *indirect* contribution by the process of augmenting its earnings state, $X(t+1)$; the weighting factors are, respectively, $k(t)$, which represents the present value of a marginal change in the firm's time t dividend and external equity acquisition decisions, and the sum of $k(\tau)$, $\tau = t+1, \ldots$, which is the present value of a marginal change in the firm's net income stream. Indeed, this is *exactly* what is meant when it is said the firm has a static investment and financing problem. To the degree that the firm pays dividends and does not acquire external capital in any period, it operates to increase $V(0)$ directly, but simultaneously reduce the potential indirect contribution to value via future earnings. In a reverse manner, the firm might alternatively choose to reduce its direct, but increase its indirect, contribution to value. A "proper balance" in the two effects is, of course, necessary for optimality. The maximum principle yields a precise statement of the firm's multiperiod investment and financing problem in a derived one-period equivalent by, most importantly, supplying the proper weighting values to these direct (immediate) and indirect (future) effects.

Stationarity conditions for the maximization problem given by (15) require at each period of time that

$$(16a) \quad -k(t) + \lambda(t+1)A(t)\frac{\partial \phi(t)}{\partial I(t)} = 0$$

$$(16b) \quad -k(t)M(t) + \lambda(t+1)A(t)\frac{\partial \phi(t)}{\partial E(t)} = 0$$

where $M(t)$ is the marginal external issue market value (rate), $\partial[\delta(t)E(t)]/\partial E(t)$. The solution to these equations are necessary and sufficient for a unique maximum to the problem if $H(t)$ is strictly concave. This property is generally assumed since ϕ is typically subject to diminishing marginal returns, and as $E(t)$ rises the marginal external issue market value will typically increase (meaning the issue needs to be "sweetened" at an increasing rate with its size).[10]

With regard to structure, a key property of the solution equations is their "decomposition" of the firm's decisions over time. In properly imputing a value to future earnings by the intertemporal shadow value $\lambda(t+1)$, each period's decisions are developed such that they can be optimally and "time-independently" undertaken. In an important way this specific feature of the solution technique distinguishes the current analysis from earlier studies which decouple the firm's time sequence of decisions more simply and restrictively by requiring that economic conditions in each

[10] Let $\phi_{II}(t)$ and $\phi_{EE}(t)$ be the second partial derivates of $\phi(t)$ with respect to $I(t)$ and $E(t)$, and let $D_\phi(t)$ be the Hessian determinant of $\phi(t)$ by those decision variables. Sufficiency conditions particularly require (16) to hold, $\phi_{II}(t)<0$, $\phi_{EE}(t)<k(t)(\partial M(t)/\partial E(t))$, and $\partial M(t)/\partial E(t) > D_\phi(t)/k(t)\phi_{II}(t)$. With diminishing marginal transactions costs for external equity $D_\phi(t)<0$ and the last condition on the minimal rate at which the marginal external issue market value increases must be assumed.

period be identical with those of every other.

Written more compactly, a maximum for shareholder value requires the firm at each period of time to select $I(\mathrm{t})$ and $E(\mathrm{t})$ financing to solve

$$\text{(17a)} \qquad \frac{\partial\phi(\mathrm{t})}{\partial I(\mathrm{t})} = Z(\mathrm{t})^{-1}$$

$$\text{(17b)} \qquad \frac{\partial\phi(\mathrm{t})}{\partial E(\mathrm{t})} = M(\mathrm{t})Z(\mathrm{t})^{-1}$$

where for notational convenience in the sequel $Z(\mathrm{t})$ is introduced, being defined as

$$\text{(18)} \qquad Z(\mathrm{t}) \equiv A(\mathrm{t}) \sum_{\tau=\mathrm{t}+1}^{\infty} \frac{k(\tau)}{k(\mathrm{t})}$$

$Z(\mathrm{t})$ will be termed the *adjusted* sum of *forward* discount factors.[11] The decision rules given by (17) are thus not myopic since they involve the parameters of future periods, and static theories of the firm's investment and financing problem are invalid unless they employ these proper intertemporal prices.

The following two sections are concerned with the content of equations (17) as optimal investment decision rules for the firm and for the implications they have with regard to the uniqueness of the firm's financing "package."

1. *Optimal Investment Decision Rules*

Notwithstanding Lintner's "current earnings yield" decision rule as a cutoff rate for investment owing to his particular definition of earnings, the familiar "valid and appropriate" criterion for determining the optimal size capital budget has the firm investing until its marginal internal rate of return equals the *constant* external market discount rate.[12] In extension to this traditional rule, the prescriptions of equation (17) are more generally appropriate, for they permit a freely given time structure for the firm's discount rate and further accommodate situations with nonneutral technical change.

It might be replied that current theories do permit a time-varying discount rate structure. For, the most commonly employed model of the firm's intertemporal investment and financing problem develops, by construction, an "equivalent composite" market discount rate, r_c, as "the" root of the equation

$$\sum_{\mathrm{t}=0}^{\infty} \frac{1}{(1+r_c)^{\mathrm{t}+1}} = \sum_{\mathrm{t}=0}^{\infty} \frac{1}{\prod_{\tau}^{\mathrm{t}} [1+r(\tau)]}$$

When this technique is used, however, the effect of the short rates, $r(\tau)$ for *all* $\tau=0, 1, 2, \ldots$, are embodied in r_c and particularly such that the weight given early periods in the horizon is greater. Thus, when the compositing scheme is used to simplify the problem the "invest-down-to-the-constant-market-rate" decision rule for an equity cutoff is affected by the market rates of all prior and future periods. In contrast, the decision rules developed here —equations (17)—properly show that only *future values* of the discount rates are relevant as a basis for establishing the proper marginal return from equity. In a reverse fashion, the form of $A(\mathrm{t})$, see equation (6), as it enters these decision rules means that only *prior* earnings-technical adjustment affects the optimal equity "cutoff" with no future values, or expectations of them, being relevant.

[11] Note:

$$\sum_{\tau=\mathrm{t}+1}^{\infty} [k(\tau)/k(\mathrm{t})] = \frac{1}{1+r(\mathrm{t}+1)} + \frac{1}{[1+r(\mathrm{t}+1)][1+r(\mathrm{t}+2)]} + \ldots$$

where $r(\mathrm{t}+1)$ is the market discount *rate* of period t+1. Thus, this is properly a *forward* sum of discount factors, each element discounting back to the end of period t.

[12] See Miller for a defense of this rule, but also a warning that it is based on assumptions which are "terribly treacherous."

Turning directly to an inspection of equations (17), the decision rules for an optimal investment program require: 1) that the marginal return to zero-transactions-cost internal equity, $\partial\phi(t)/\partial I(t)$, equal the inverse of the adjusted sum of forward discount factors and 2) that the marginal return to external equity issues, or any equity having transactions costs associated, $\partial\phi(t)/\partial E(t)$, always equal the *prevailing* marginal external issue market value times that same inverse of the adjusted sum of forward discount factors. Future expectations of an equity issuance premium or discount are immaterial. Optimal $I^*(t)$ and $E^*(t)$ follow from the simultaneous solution of equations (17).

If $\delta(t)\equiv 1$, implying that shares are issued and subscribed at market value, and marginal transactions cost are positive for any external issue, then external sources of funding will not optimally be employed, $E(t)\equiv 0$. External financing will only be used in the circumstances where a range, over $E(t)$, exists such that the marginal external issue market value is less than the marginal contribution of an external issue to investable funds. (The issuance of stock at a premium to market value results in a *gain* to existing shareholders and thus affects the tradeoff between internal and external generated equity.) Letting J be the investable portion of externally acquired funds (net of transactions costs) then $\partial\phi/\partial E=\partial\phi/\partial J\cdot\partial J/\partial E$ and $\partial\phi/\partial J\equiv\partial\phi/\partial I$: thus, at the optimum $M(t)=\partial J(t)/\partial E(t)$, the equality of the external issue marginal market value and marginal contribution to investable funds, is necessary.

These new rules are consistent as extensions to the standard (comparative dynamic) treatments of the firm's optimal investment decision. Indeed, it is of interest to see the manner in which they specialize under the several restrictions of prior studies. Particularly, suppose the commonly employed circumstance of constant market discount rates, neutral earnings-technical adjustment, and all new shares issued precisely at market price. From equation (18) it follows that $Z(t)=1/\bar{r}$, where $\bar{r}$ is the constant discount rate. Further not distinguishing acquired equity to permit associated transactions cost implies $I(t)+E(t)\equiv B(t)$, where $B(t)$ is an investment aggregate. Thus, the earnings-change function simply becomes $\phi(t)=\phi[B(t)]$, and the "minimum" cost financing can be subsequently chosen. With these restrictions, equations (17) degenerate to the familiar rule that $\partial\phi(t)/\partial B(t)=\bar{r}$ and, as common, the rule simply requires that the firm optimally invest "down" to *the* external market rate.

2. *Dividend Relevancy and Conditions for a Unique Financing Program*

Turning now to the dividend relevancy question popular in both the theoretical and empirical literature, the form of the present model makes it possible to adduce more precisely the conditions under which a unique dividend and financing program exists. As a precursor to complete conditions it is first convenient to sketch the essence of the Miller-Modigliani proof of the immateriality of the equity financing package. (A representative time t is used, but, of course, t could indicate any and every period.)

Specifically, as M-M, we wish to derive the conditions for changes in $I(t)$ and $E(t)$ which lead to a null effect on $V(0)$. The differential of $\bar{V}(0)$ according to $I(t)$ and $E(t)$ can be simply formed from equation (8) and set to zero yielding

$$\text{(19)}\quad \left[Z(t)\frac{\partial\phi(t)}{\partial I(t)}-1\right]dI(t)=\left[Z(t)\frac{\partial\phi(t)}{\partial E(t)}-M(t)\right]dE(t)$$

If we suppose that $\delta(t)\equiv 1$, $M(t)\equiv 1$ and $\delta\phi(t)/\partial I(t)\equiv\partial\phi(t)/\partial E(t)$, which is surely

guaranteed by the M-M assumptions of "perfect" capital markets, then the conclusions are subsequently clear: so long as the firm substitutes retained earnings for external equity on a one-to-one basis, or conversely, the firm's initial value will not change.[13] And, since dividends are the complement of retained earnings, the specific payout at any point in time is immaterial in establishing the value of the corporation.

The structure of the present model and its solution equations offer a convenient means to extend and clarify the M-M conditions. Interpreting the "rational behavior" postulate of M-M, p. 412, particularly to mean that the firm not only desires but positively acts to achieve maximum shareholder wealth, it is seen that the conditions for a unique, optimal financing program to exist are indentical to those under which a unique solution exists for equations (17). This existence question follows directly from the implicit function theorem: under circumstances in which the Jacobian of equations (19) is nonsingular in the neighborhood about the candidate optima, there exists a solution for $I^*(t)$ and $E^*(t)$ solely in terms of model parameters. The relevant Jacobian is merely the Hessian of $H(t)$ by the two decision variables. As a result, the role of both the firm's investment possibilities and transaction costs in specifying $\phi(t)$ and the properties of the external issue discount/premium function, $\delta(t)$, are important to the question of a unique financing package. Using subscripts to indicate partial differentiation and dropping time arguments, conditions for nonunique financing are $Z^{-1}M_E = (\phi_{II}\phi_{EE} - \phi_{IE}^2)/\phi_{II}$ at the optima. One idealized case in which these conditions hold is that of perfect markets—rationality, identical investor expectations ($\delta \equiv 1$), and no transactions costs ($\phi_E \equiv \phi_I$). These are the assumptions employed by M-M and can be simply seen to guarantee the singularity of the Hessian at the optima. It, however, should be noted that their assumptions are a sufficient, but not necessary, condition for this singularity and thus for the "irrelevancy" of dividends.

IV. Conclusions

Although the economic implications of the foregoing model and its development have been continuously noted, several stand out for special emphasis. First, and at the center of the entire analysis, is the precise statement of the firm's financing problem given by the requirement to maximize the Hamiltonian. The importance of this condition arises not from the fact that "direct" and "indirect" effects must enter into the investment and financing dedecision, and that these must be compromised, but, rather, it stems from the explicit weights given these two effects. A second key implication of the analysis is that dividend policy does generally affect the maximizing firm's value. Only under those specializing assumptions which give singularity to the relevant second-order Hessian determinant are dividends, or the financing package, irrelevant. Finally, the standard "invest-down-to-the-external-discount-rate" theorem has been extended to further specify the particular investment and financing program which is optimal, to accommodate an index of technical progress, to permit external equity to be acquired at a premium or discount with respect to its market value, and to reflect nonconstant external discount rate structures.

These and the several other conclusions of the present study importantly result from a generalization of prior models and not, as common, from considering further restrictive conditions. Thus, perhaps more

[13] Of course, if the firm is maximizing $V(0)$ under these specific assumptions then $\partial\phi/\partial I = \partial\phi/\partial E = Z^{-1}$ and the rate of substitution is ambiguous. We consider this case in the sequel. Also, note that if $\delta \neq 1$ then the rate of substitution will not be one-to-one.

useful than any of the specific implications derived, the current model lays a firm groundwork for further study. For, by giving a more analytic and flexible structure to the firm's decision problem a new basis is laid for extending the set and treatment of involved variables. An obvious first step in this direction would be to include debt financing as an argument in ϕ and then permit functional dependence between the firm's decisions (and concomitant changes in leverage ratio) and its appropriate external discount rate. Also the introduction of random elements for the development of optimal adaptive decision strategies might be highly fruitful.

Private Demands for Public Goods

By THEODORE C. BERGSTROM AND ROBERT P. GOODMAN*

Goods and services which are publicly supplied generally share two features. Costs of these commodities are divided among members of the community. Decisions about quantities to be supplied are made collectively. Somehow, from a community consisting of many individuals with different tastes, different amounts of wealth, and conflicting interests, a single decision must emerge. Quantities must be determined and costs divided in some way.

In this study we develop a method for estimating demand functions of individuals for municipal public services. Demand will depend on the traditional economic variables, price and income, as well as on certain demographic characteristics of the individual and the city in which he lives. Knowledge of individual demand functions would be useful for many purposes. Such uses include:

1) Prediction of the outcomes of alternative political decision methods and tax structures in a particular city.

2) Computation of tax structures and expenditure levels which satisfy certain preference-based normative criteria such as the Lindahl equilibrium. This would enable one to make statements about whether "too many" or "too few" public goods are actually provided and whether tax burdens are divided "equitably" relative to the norm employed.

3) Investigation of whether there are "scale economies" to city size in the production of public services.

4) Prediction of the effects of projected changes in values of economic and demographic variables on quantities of public goods to be supplied.

In the case of privately purchased commodities, it is in principle possible to observe directly the choices made by individuals belonging to a particular demographic group under alternative price and income situations. This is not in general the case with publicly supplied commodities.[1] One is, however, able to observe the choices made by many distinct municipalities. Employing rather simple assumptions on the nature of the political process in each municipality, this information can be used to make inferences about the responses of individual demands for municipal services to price, income and other variables.

As an illustration of how this may be done, consider the following assumptions:

I. Units of measurement for a given municipally supplied commodity can be chosen in such a way that each municipality j is able to supply the commodity at constant unit cost q_j.[2]

* Associate professor, department of economics, Washington University, St. Louis and economist, department of economics and human development, State of Maryland, respectively. This research was done at Washington University and was in part supported by NSF Research Grant GS-3070. A more detailed presentation of the results is available on request. We are grateful for assistance and helpful comments from James Barr, Banarsi Dhawan, John Legler, and Richard Meadows.

[1] This problem and related issues are well discussed by James Buchanan and Gordon Tullock.

[2] This will be possible even if communities produce public goods using some local inputs whose prices may differ from place to place, so long as a) all municipalities have identical, homothetic production functions and b) all municipalities face horizontal supply curves for inputs. To see this, simply choose output units so that production takes place at constant returns to scale and observe that for any community, a change in output so measured results in a proportional change in total costs. Of course unit costs may differ from place to place, but in each place unit costs are constant with respect to output.

II. For each consumer i there is a tax share τ_i such that i must pay the fraction τ_i of the total cost of municipal expenditures in his community. Consumer i's tax share may depend on his wealth, his income or other individual characteristics, but it does not vary with the size of municipal expenditures nor with the way in which he expresses his desires for municipal services.

III. Any consumer i living in municipality j is aware of his "tax price," $\tau_i q_j$ and is able to determine the quantity of the municipal commodity which he would choose for the community given that he must pay the fraction τ_i of its total cost. To do so he needs only to maximize his own preferences subject to a linear budget constraint where his tax price for the municipal good is $\tau_i q_j$.

IV. In each municipality, the quantity supplied of the municipal commodity is equal to the median of the quantities demanded by its citizens.

V. In each municipality the median of the quantities demanded is the quantity demanded by the citizen with the median income for that municipality.

Observe that if Assumptions IV and V are true, the quantity of municipal commodities chosen by any community is the amount which is desired by the consumer with the median income for that community. Our assumptions about the constancy of τ_i and q_j, enable us to treat the expenditures of any municipality as an observation on the demand curve of a consumer with the median income for this municipality, where the price he pays for public goods is proportional to his tax share.[3] Assumptions I–IV are proposed and studied by Howard Bowen and independently by James Barr and Otto Davis. Assumption IV will hold if, for example, there is a majority voting system in which the quantity selected is such that half the population wants more and half the population wants less than that quantity.

DEFINITION: *An allocation satisfying I–IV will be called a Bowen equilibrium.*

Circumstances under which V is justified will be discussed below. It will also be demonstrated that our estimation procedure applies under somewhat weaker assumptions than V.

I. Estimating Procedure

Our sample consists of 826 municipalities with 1960 populations between 10,000 and 150,000, located in 10 states.[4] Multiple regression is used to fit a function of the form:

$$\log E = c + \alpha \log n + \delta \log \hat{\tau} + \epsilon \log \hat{Y} + \sum_{i=1}^{k} \beta_i X_i$$

The symbols are defined as follows:

E = The expenditures of a municipality on a specified category of municipal service. In particular, separate regressions were run for the following definitions of E.

(a) E = Police expenditures.

[3] A similar approach to the estimation of individual demands for public goods is suggested by Robin Barlow, by James Barr and Otto Davis, and by Thomas Borcherding and Robert Deacon.

[4] The states included and the number of observations from each are shown in Table 1. Our choice of states was determined in part by availability of data and in part by a desire to include states which had a large number of municipalities. The main limitation of data is the availability of figures on equalized assessed valuation by municipality. (Connecticut was excluded because of a lack of other demographic data.) There are several "small" states for which comparable data is available but which were not studied because of limitations of time. Results are reported for all states which were studied. It was believed that cities with populations exceeding 150,000, because of their relative small number and because of the more detailed information available concerning them, would be more appropriately treated in a separate national cross-section study. Places with populations below 10,000 were excluded because of a lack of comparable data.

(b) E = Parks and recreation expenditures.

(c) E = Total municipal expenditures excluding education and welfare.

n = The number of households in a municipality.

$\hat{\tau}$ = The tax share of the citizen with the median income for a municipality.

$\hat{Y}$ = Median income in a municipality.

The X_i's consist of the values of several descriptive social and economic variables for a municipality. These variables will be discussed below. As argued previously, Assumptions I–V would permit us to use the expenditure of any municipality as an observation of the quantity demanded by one of its citizens whose income is $\hat{Y}$ and whose tax share is $\hat{\tau}$.

If all municipally supplied commodities were pure public goods as defined by Paul Samuelson, the use of a public commodity by any consumer would not reduce its usefulness to others. If this were the case, the size of a city would affect the quantity of municipal commodities only indirectly through the tax share. In larger cities, costs would be divided among more citizens and tax shares would tend to be smaller, hence individuals would tend to vote for more public commodities.

If there is crowding of municipal services, population size may also have a direct effect on individual demands. We suggest here a simple model of crowding which lends a natural interpretation to our population coefficients. Suppose that the usefulness of a public facility to any individual is determined by a function of the form $Z^* = n^{-\gamma}Z$ where n is the number of people sharing the good and Z is the quantity of the public good. Let the utility function of any individual, i, be of the form $u_i(X_i, Z^*)$ where X_i is the quantity of private goods which he consumes. If $\gamma = 0$, the public good is a Samuelsonian pure public good. If $\gamma = 1$, the individual's preferences are as if he received and enjoyed only the fraction $1/n$ of the total amount of the public good. Suppose the unit cost of the private good is p, the unit cost of the public good is q, and the tax share of consumer i is τ_i. Then his demand function is found by maximizing $u_i(X_i, Z^*)$ subject to

$$X_i + \tau_i qZ \leqq Y_i$$

or equivalently subject to

$$X_i + \tau_i qn^\gamma Z^* \leqq Y_i$$

Thus, determination of his demand function for Z^* is formally equivalent to finding an ordinary demand function where the price is $\tau_i qn^\gamma$. Let us suppose that there are constant income and price elasticities δ and ϵ for the commodity Z^*. Then the demand function for Z^* is of the form,

$$c[\tau_i qn^\gamma]^\delta Y_i^\epsilon$$

The quantity of Z demanded is n^γ times the quantity of Z^* demanded. Hence, his demand for Z is

$$n^\gamma c[\tau_i qn^\gamma]^\delta Y_i^\epsilon = cq^\delta \tau_i^\delta Y_i^\epsilon n^{\gamma(1+\delta)}$$

Thus, the coefficient, α, for the elasticity of demand with respect to population could be interpreted to be $\gamma(1+\delta)$.[5]

If γ were nearly zero, there would be substantial economies to larger city size since in larger cities, more consumers could share in the costs of municipal commodities with only minor crowding effects. Where γ is about one, the gains from sharing the cost of public commodities among persons are approximately balanced by the disutility of sharing the facility among more persons.

The values of the auxiliary variables

[5] A very similar analysis of crowding is presented by Thomas Borcherding and Robert Deacon. Notice that if $\gamma = 1$, the demand equation reduces (in *log* form) to $log\ (E/n) = log\ c + \delta\ log\ (q\tau_i n) + \epsilon\ log\ Y_i$. In this case we could consider demands for *per capita* quantities as a function of tax price *multiplied by population* and of income.

$X_1, \ldots, X_k$, may have two distinct kinds of effects on the expenditure decision of a municipality. Some variables appear to describe characteristics of a city which have fairly uniform effects on the demands of all its citizens for public services. Other variables seem to enumerate a portion of the population which may either have different tastes from the remainder of the population or pay a different tax share than persons with similar income. Examples of the former type are density and employment-residential ratio. Examples of the latter type are percent owner occupied, and percent of population older than 65. In practice, it is difficult to make this distinction in an unambiguous way. (How would one classify population change or percent nonwhite?) The first type of effect presents no difficulties for our method of analysis. The second type presents problems which will be discussed below. Since we have employed only a few of a large complex of interrelated social variables, it is difficult to attribute a clear-cut causal interpretation to the coefficients of these variables. At best, we hope that the variables which we include are adequate to eliminate substantial distortions of our estimates of price, income, and population elasticities.

II. Measurement of Variables

With the exception of the tax share variable, all of our data are available from standard sources. Roughly speaking, the income and demographic data are available from the 1960 census of population, while the expenditure data are from the 1962 census of governments.

We measure the quantity of municipal services by dollars of expenditure, median income in dollars, and the tax price of the median income consumer by his tax share. For this procedure to be literally consistent with our interpretation of the regression coefficients of income and tax share as price and income elasticities, we must assume that prices of private goods and unit costs of public goods are the same in each community observed. It is probably not unreasonable to assume that most of the supplies purchased by municipalities are purchased competitively in the same national market. But some of the inputs of municipal operations will be local labor and local land. Prices of these inputs may differ between communities. Local prices of *private* goods will also depend on local factor prices. Ideally we would like to deflate income by a local price index for all goods and deflate public expenditures by a local price index for public goods. We also would wish to use as our tax price variable the tax share *multiplied by the ratio of local public goods prices to local private goods prices.* Such local price indices are not, however, currently available.[6] It might not be unreasonable to suppose that the ratio of prices of public to private goods differs little between cities. In this case error enters our equation only because of the lack of a local price deflator for our income and expenditure figures. If the income elasticity of demand is close to unity, this will not seriously bias our estimates.[7]

[6] It would be possible in principle to construct such indices, using consumer budget studies, technical information about input requirements, and data on local factor prices.

[7] If q and p represent local prices for public and private goods, respectively, then the equation we would like to estimate is:

$$\log \frac{E}{q} = c + \alpha \log n + \delta \log \left(\hat{\tau} \frac{q}{p}\right) + \epsilon \log \left(\frac{\hat{Y}}{p}\right) + \Sigma \beta_i X_i$$

Rearranging terms we have:

$$\log E = c + \alpha \log n + \delta \log \hat{\tau} + \epsilon \log \hat{Y} + \Sigma \beta_i X_i + (1 + \delta) \log q - (\delta + \epsilon) \log p$$

This expression differs from the equation we estimated only by the final two terms. If q and p were uniform across cities, the omitted terms would affect only our intercept and not our estimates of elasticities. If the ratio of p to q were the same in every community then

Measurement of the tax share variable presents some conceptual and practical difficulties. We should like our demand equation to represent the response of individuals to the prices and incomes which they *perceive*. If one were to ask several individuals what their tax shares are, we suspect that few would be able to answer the question sensibly without more reflection than usually takes place before voting. Nevertheless, they may have knowledge which is for our purposes equivalent. For example, if a citizen knows his municipal tax bill and believes that his taxes will change in proportion to municipal expenditures, he will know the cost to him of a given percentage change in municipal expenditures. Moreover, it is often the case in municipal elections that an expenditure proposal is combined with a proposed change in property tax rates. A citizen who has some knowledge of the assessed value of his property can then determine the cost to him of the proposal.

It seems likely that although individuals have some notion of the cost of a proposal to them, their perceptions of tax shares may be quite imprecise. We formalize this idea by assuming that the perceived tax shares of individuals are independently distributed random variables with expected values equal to the actual tax shares. It turns out that in large populations the effects of independent errors of perception tend to cancel each other and that statistical distortions in our estimates from this cause are likely to be negligible. A formal statement of this proposition and its proof is offered in the Appendix.

In most cities sampled, more than half of locally generated revenue comes from the property tax. Property tax revenue is raised largely from taxes on real property (buildings and land) with the remainder derived from personal property taxes. To estimate the share of the tax on real property which is paid by a citizen with the median income for his community, we assume that in any municipality, the citizen with the median income lives in and owns the house with median value and that his house constitutes his entire holdings of real property. For each municipality, median house value is found in the 1960 U.S. Census of Housing. Tax rates and ratios of assessed to market value are determined for each community from information compiled by the states. The tax bill on the house of median value is then computed. This figure is divided by total property tax revenue for the municipality to produce an estimate of the share of real property taxes paid by the consumer with the median income.[8] It is assumed that the consumer with the median income pays the same share of other municipal revenues as he does of the real property tax. This is purely an assumption of conve-

the last two terms of the above equation would reduce to $(1-\epsilon)$ $\log p$ (plus a constant). If ϵ is near unity, then this term becomes insignificant.

[8] Those differences in median tax share from place to place which are not attributable to differences in population are largely due to differences in the amount of commercial and industrial property. Implicit in our procedure for estimating the tax share of the median consumer is the assumption that the burden of property taxes paid by commercial and industrial establishments is borne by persons living outside the municipality (or at least by an electorally insignificant portion of the cities' population). The assumption that individuals believe that their tax shares will not be altered if expenditures increase implies that they assume that the percentage of total revenue which can be extracted from commercial and industrial property will not change with changes in total revenue and expenditures. This may be somewhat unrealistic. A more thorough investigation might consider the question of the ability of a municipality to extract locational rents in an economy where the decision of a firm to locate in the municipality depends on levels of taxation and the quantity and composition of municipal taxation. Very little of the revenue for the services we study comes from other governments. The only exception is local highway expenditures for which about 15 to 25 percent of revenue comes from state collected funds. Even here, the transfers seem generally to be of the lump sum type, thus producing only a small income effect and no substitution effect.

nience which should be modified wherever better information is available.[9]

Although independent errors of perception by individuals are unlikely to have substantial effects on the parameter estimates, we are left with the problem that our own estimates of tax prices may differ substantially from the "true" tax prices. There are several reasons for this. One problem is that the accuracy of our estimates depends on the accuracy of the assessment to market value ratios computed by state equalization boards. These may be subject to substantial error. The assumption that the tax share of the consumer with median income is equal to his share of the property tax introduces further possibilities for error, as does the assumption that total unit costs of public goods are the same in all municipalities. Finally, there may be systematic nonindependent errors of perception in a community depending on the information made available to its citizens by the municipal authorities. If there are errors of measurement in the calculation of tax shares, the regression coefficients will be biased estimators and tend to underestimate the absolute value of the price elasticity. We therefore will compute maximum likelihood estimates of the price elasticity under some alternative assumptions about the measurement error.

III. Legitimacy of the Estimating Procedure

Suppose that the tax share of an individual is determined by his income and by the community in which he lives. For a citizen of municipality i, with income Y, the tax share will be written $\tau^i(Y)$. Let the demand for a public commodity by a citizen of municipality i be determined by the function $D(Y, \tau^i(Y), n^i, X^i)$ where n^i is the population and X^i a vector of values of variables describing municipality i.

To examine the effects on demand of differences in income within a given community, compute the total derivative of demand with respect to income. This is $dD/dY = \partial D/\partial Y + (\partial D/\partial\tau)(\partial\tau/\partial Y)$. Transforming this result into elasticity form, we have $(Y/D)(dD/dY) = \epsilon + \delta\xi$ where ϵ is the ordinary income elasticity of demand, δ is the price elasticity of demand, and $\xi \equiv (Y/\tau^i)(\partial\tau^i/\partial Y)$ is the elasticity of the tax share with respect to income. If for all values of Y, $\epsilon + \delta\xi > 0$, then the higher a citizen's income the more he will demand of the municipal commodity, if $\epsilon + \delta\xi < 0$ the quantity demanded decreases with income.[10] In either case, quantity demanded is a monotone function of income. It would then follow that the quantity demanded by the citizen with the median income in any municipality is also the median quantity demanded in that municipality. In such cases if we are willing to assume that the municipality is in Bowen equilibrium, the estimating procedure suggested in the previous section will give us reasonable estimates of price and income elasticities of demand.

If, however, $\epsilon + \delta\xi$ is positive for some levels of income and negative for others, the quantity demanded will not be a monotone function of income. In this case the median quantity demanded will not in general be the quantity demanded by the consumer with the median income.

For example, in Figure 1, if the incomes of half the population lie in the intervals OA and BC while the other half of the population has incomes in the interval AB, then the Bowen equilibrium quantity will be OE rather than OD, which is the quantity desired by the consumer with median

[9] It is generally quite difficult to assign the burden of nonproperty taxes. In the case of Pennsylvania there is a municipal income tax for many cities. We have included this tax in our computations of tax shares.

[10] These notions are also introduced by Buchanan (1964).

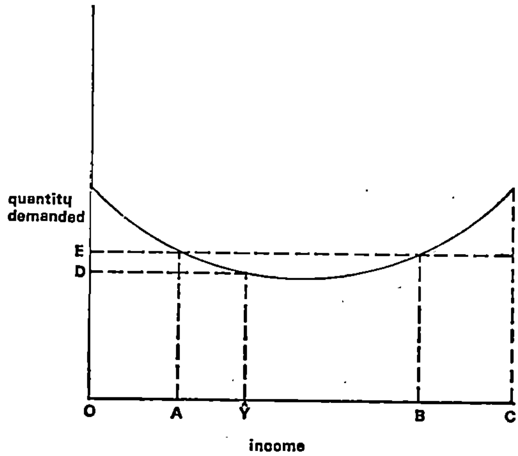

FIGURE 1

income $\hat{Y}$. Obviously, with alternative tax structures, a wide variety of cases can be constructed in which the quantity selected exceeds or falls short of the quantity demanded by the citizen with median income. If there were frequent and substantial variations of this kind, our procedure would not be expected to give reasonable estimates of the income elasticity of demand.

Similar difficulties arise if there are differences in tastes or in tax share functions for different segments of the population of a municipality. Suppose, for example, that renters believe (whether rightly or wrongly) that they do not pay the entire property tax on their housing. Their perceived tax shares will then be lower than those paid by home owners. One would expect them to vote for more public services than their home-owning counterparts. The half of the population desiring the larger amount will consist of proportionally more renters than home-owners. There is again no reason to expect the median quantity desired to be the quantity desired by the consumer with the median income. In general, the Bowen equilibrium quantity will depend on the shape of the entire income distribution functions of each group.

Here, however, things are not quite as chaotic as they may seem. One can make perhaps not grossly unrealistic assumptions which would allow him to use the estimating procedure previously outlined. Matters are greatly simplified if we make certain regularity assumptions about income distributions. We present a theorem which allows us to use the estimating procedure of the previous section even though there may be differences in tastes or in tax share schedules within communities.

Consider a set M of cities. Let P^i be the set of consumers in city i where $i \in M$. Let $\{P_1^i, \ldots, P_n^i\}$ be a partition of P^i, where λ_j^i is the ratio of the number of members of P_j^i to the number of members of P^i. (For each $i \in M$, $\sum_{j=1}^n \lambda_j^i = 1$.) Let F_j^i be the cumulative income distribution function for P_j^i. Thus, $F_j^i(Y)$ is the ratio of the number of members of P_j^i with incomes not exceeding Y to the total number of members of P_j^i.

DEFINITION: *Income distributions are said to be proportional in M (with respect to the partition $\{P_1^i, \ldots, P_n^i\}$) if there exist functions F_j, such that for each $i \in M$ there is a real number $k_i > 0$ where, for all $j = 1, \ldots, n$, $F_j^i(Y) \equiv F_j(k_i Y)$.*

The following remark may help to give intuitive meaning to this definition. Suppose that in municipality 1, the cumulative income distributions for the subsets $P_1^1, \ldots, P_n^1$, are $F_1^1, \ldots, F_n^1$. (These functions need not bear any similarity to each other.) Suppose that income distributions in any other city $i \in M$ are the same as the income distributions in city 1 would be if the income of every citizen of city 1 were multiplied by some number k_i. Income distributions would then be proportional in M.

We can now state Theorem 1. A proof is supplied in the Appendix.

THEOREM 1: *Suppose that for each city*

$i \in M$, the population is partitioned as in the above discussion. Let income distributions be proportional in M with respect to the partition $\{P_1^i, \ldots, P_n^i\}$. Let the tax shares of members of P_j^i with income Y_i to be determined by a function of the form $\tau_j^i(Y) = \tau^i \tau_j Y^\xi$ (where τ^i and τ_j are constants depending on an individual's community and his subset). Let the demands for a public good of a member of P_j^i with income Y be determined by a function of the form $c_j f(X^i)[\tau_j^i(Y)]^\delta Y^\epsilon$. Suppose also that income distribution functions satisfy certain continuity assumptions (which are made explicit in the proof) and that $\epsilon + \xi\delta \neq 0$. Then the median quantity, $\hat{E}^i$, of a public good demanded by citizens of i is determined by a function of the form

$$\hat{E}_i = h(\lambda_1^i, \ldots, \lambda_n^i) c_1 f(X^i) [\hat{\tau}_1^i]^\delta [\hat{Y}^i]^\epsilon$$

where h is a continuous real valued function of the vector $(\lambda_1^i, \ldots, \lambda_n^i)$, $\hat{Y}^i$ is the median income for the entire city i, and $\hat{\tau}_1^i$ is the tax share of a member of P_1^i whose income is $\hat{Y}^i$.

The point of the theorem is that it allows us to use $\hat{Y}^i$ as the only variable describing income in city i and to use the coefficient ϵ as an estimate of income elasticity. Without the assumption of proportionality of income distributions, the quantity $\hat{E}^i$ would generally depend on the detailed structure of income distribution in each subset, P_j^i.

Nothing is said here about the functional form of h, which in general will be rather complicated. However, if we are willing to approximate the effect of the λ's as either linear or *log*-linear, we can estimate the income and price elasticities from cross-sectional observations of the expenditures of municipalities, their median incomes, and the tax shares of consumers of one type with the median income for the municipality. It is this result which justifies, for example, our use of "percent owner occupied" as an independent variable, our use of the tax share of a home-owner with the community median income as the tax share variable, and median income for the community as the income variable.

IV. Results of the Regressions

We were pleased to discover that our estimates of income elasticity were usually significant and positive and the estimates of price elasticity were usually significant and negative. In no case was an estimated elasticity coefficient both significant and of perverse sign. The results for the individual states are reported in Tables 1–3. Table 4 reports the results when all observations are pooled. For these regressions, dummy variables were used to allow the regression line a different intercept for each state. Although the results for the separate states are roughly similar, and there is considerable regularity in the signs of coefficients, the F-test would lead us to reject the hypothesis that mean square errors of the estimates are reduced by pooling the data. (See C. Toro-Viscarrondo and T. Wallace.) Some of the states could be combined successfully according to this criterion. However, rather than apply *ad hoc* methods, we would prefer to defer further efforts at pooling data until better measurement and perhaps better specification of variables is made. Ideally, we would hope that with proper measurement, it will be discovered that the coefficients of our dependent variables are not significantly different between the states. For the present we must settle for the rough similarity which we do find. It may nevertheless be convenient occasionally to use our estimates of the coefficients from the pooled regressions as crude summaries of our results.

Estimates of γ, the crowding parameter, were made by computing the ratio $\alpha/(1+\delta)$ where α and δ are the estimated elasticities of expenditures with respect to population and tax share, respectively. For most

states, the estimates of γ for police expenditures and general expenditures are strikingly close to unity. We applied an F-test to determine whether to reject the hypothesis that the linear restriction $\alpha=1+\delta$ applies. In all states but Illinois and in the pooled regression, the test strongly suggests that the null hypothesis should be accepted for police expenditures. For general expenditures, we would have to reject the null hypothesis at the 5 percent level for about half of the states and for the pooled regression. However, in all cases except Illinois we would reject the hypothesis that $\gamma \leq 1$. The test also suggests that for parks and recreation expenditures, γ is one or greater.

Some economic implications of the values of the price and income elasticities and the coefficient, γ, will be discussed in the next section.

A few speculations about the effects of some of the auxiliary variables may be justified by the degree of regularity with which the same signs appear. The differences in their sizes and the possibility of correlation with other more "truly explanatory" variables does suggest caution in making causal interpretations. The reader is, of course, invited to make his own speculations.

Percent owner occupied: As argued earlier in this paper, it may be that renters do not believe that they pay the entire property tax on their housing, and tend to vote for more public expenditures than homeowners with the same income. If this is the case, one would expect the negative coefficient which we find for this variable.

Employment-Residential ratio: Communities with high values for this variable would tend to have a large amount of com-

mercial or industrial activity. It may be that larger amounts of public services must be provided in order to attract and retain such activity. This might explain the positive effect which we find.

Population change: Cities which have grown rapidly may not yet have achieved a political equilibrium. Time is required for a rapidly growing city to gain a political consensus for expanding public services. Inertial effects may also result in larger expenditures in places with declining population. This might explain our negative coefficient.

Percent of population over 65: The life cycle hypothesis would predict that persons over 65 years of age tend to spend a larger portion of their current income on current consumption than younger people. If demand for public goods as a fraction of total demand does not diminish with age then one would expect an aged person to demand a larger quantity of public goods than a younger person with the same income and tax share. The effect of this variable would then be positive, which is what we usually find.

The variables, percent nonwhite, percent who lived in the same house from 1955 to 1960, and population density, frequently had coefficients significantly different from zero. We have no particularly compelling explanation for the pattern of signs which emerges. Although these variables are included in the regressions reported, the size and significance of the other coefficients are not substantially altered when we exclude them.

TABLE 5

If 95 percent of the measured values $\hat{T}$ lie in the interval [,] where T^* is the "true" value of median tax share	$[.5T^*, 2T^*]$	$[.57T^*, 1.75T^*]$	$[.66T^*, 1.5T^*]$	$[.75T^*, 1.33T^*]$	$[.9T^*, 1.11T^*]$	No error
then the maximum likelihood estimate of δ is	$-.83$	$-.44$	$-.30$	$-.26$	$-.24$	$-.23$

We experimented with the use of some other variables, including population per household, median school years completed, percent of population less than 18 years old, whether a municipality was a suburb or not, percent of the population with annual incomes below \$3,000 and percent of the population with annual incomes exceeding \$10,000. Each of these variables proved to have statistically insignificant effects in all or nearly all of our regressions.

The fact that the variables representing percentages of populations at the extreme ends of the income distribution were almost always insignificant provides mild evidence in favor of our hypothesis that the consumer with the median income also demands the median quantity of public goods. It is of some interest to observe however, that for California, the percentage of the application with income under \$3,000 has a significant and positive effect on demand. When this variable is included, the coefficient of median income for California rises from values considerably lower than those displayed for other states to values quite similar to the others.

It was thought that perhaps our estimates would be overwhelmed by the effects of population size. In particular there is a strong negative correlation between population and tax share (because in larger cities taxes are divided among more persons). It also seemed possible that the effects of some of our variables might be substantially different in cities of different size, either due to differences in political structure or uncaptured social differences. We therefore stratified our sample into nine population subgroups. Again, our coefficients were almost all reasonable and fairly similar between groups. For no population subgroup were we able to reject the hypothesis that $\gamma=1$.

As mentioned above, we computed maximum likelihood estimates for the regression coefficients under some alternative assumptions about errors in the measurement of tax share. The only coefficient which was substantially affected was the coefficient of tax share itself. In Table 5 we report the maximum likelihood estimate of the tax share elasticity δ where there is a lognormally distributed measurement error with alternative variances.[11] These values apply to the pooled regression on general expenditures. The effects on the other regressions were similar.

V. Some Implications of the Results

The reasonable values which we find for our coefficients lend at least some support to the hypotheses which we make about political behavior. These hypotheses in turn provide a useful tool for the estimation of the effects of income, price, city size, and other social variables on demand

[11] We follow the maximum likelihood procedure suggested by John Johnston, pp. 168–70.

for public commodities. The reader would, of course, do well to maintain a degree of skepticism about the values of the coefficients which we find. Strong assumptions were made to derive the estimates. It is possible that more precise measurement of the variables and additional tests of the assumptions would result in quite different estimates of demand functions.

Here we examine some implications of the parameter values which we find. The reader is free to apply the analysis below to the implications of any alternative estimates which he prefers.

Suppose that the only real property holdings of voters are their dwellings and that the tax share of a voter is proportional to his holdings of real property. The most commonly accepted estimates of the income elasticity of demand for housing appear to be between 1 and 1.3.[12] This would imply an elasticity, ξ, of tax share with respect to income in the same range. For most of our regressions (exceptions are California and Pennsylvania) we estimate the income elasticity, ϵ, to be substantially greater than $-(1.3)\delta$. Thus, we would expect that $\epsilon+\xi\delta>0$. According to our earlier discussion one would expect that in most cities, citizens with incomes exceeding the median would vote for increased expenditures and citizens with lower incomes would vote against increased expenditures.[13]

The Lindahl solution for allocation of public goods has predictive and normative properties which are attractive to many economists. Under quite reasonable assumptions, Lindahl equilibrium exists, is Pareto optimal, and is in the core.[14] In Lindahl equilibrium, tax shares are arranged in such a way that all consumers demand the same quantity of each public commodity. It has frequently been pointed out that if an individual's stated preferences for public commodities influence his tax share, it is usually in his interest to misrepresent his preferences. This difficulty would seem to greatly reduce the practical usefulness of the Lindahl system as an allocative device. As our paper suggests, it may nevertheless be possible to gain approximate information about the preferences of broadly defined social groups if one observes the voting behavior of individuals under circumstances where it is reasonable to believe that an individual's expressed desires concerning levels of expenditure do not influence his tax share.

A Bowen equilibrium is not, in general, Pareto optimal. For "most" Bowen equilibria one could find an alternative distribution of the tax burden and alternative levels of public expenditure which would result in a Pareto-superior allocation. One might wish to ask whether a certain Bowen equilibrium results in "too little" or "too much" public goods. This question is not generally answerable on the basis simply of the Pareto criterion. As Paul Samuelson stresses, there are an infinity of Pareto optimal allocations corresponding to different points on the "utility possibility" frontier. Generally there will be different quantities of public goods for different Pareto optimal allocations. Some of these quantities may be larger and some smaller than the Bowen equilibrium quantity considered.

A more determinate normative criterion would be to compare a given Bowen equilibrium to the Lindahl equilibrium corresponding to the initial distribution of income. If voters of all incomes are to agree about the quantity of public goods to be supplied, the tax schedule must be

[12] See for example the papers by Richard Muth and Frank de Leeuw.

[13] An interesting piece of independent evidence indicating the same conclusion is provided by Harlan Hahn and W. B. Shephard's study of precinct voting in municipal referenda.

[14] See the papers of Erik Lindahl, Duncan Foley, and Bergstrom (1970).

such that $\epsilon+\xi\delta=0$.[15] For a community with known values of $-\epsilon/\delta$ and ξ, we could compute both the Lindahl equilibrium and the Bowen equilibrium if we had full knowledge of the income distribution. It is in general not possible with knowledge only of $-\epsilon/\delta$ and ξ to determine in which case the quantity of public goods is larger.

If, however, we assume that the elasticities, ξ and $-\epsilon/\delta$ are constant over all incomes, we can provide a partial answer to this question given only limited information about the income distribution. In particular, in either Bowen equilibrium or in Lindahl equilibrium the quantity supplied will be equal to the quantity demanded by the citizen with median income. To determine in which case he demands more, we need only to determine whether his tax share is lower in Lindahl equilibrium or in Bowen equilibrium. Where price elasticities are negative, the Lindahl equilibrium quantity will exceed the Bowen equilibrium quantity if, and only if, the tax share of the consumer with median income is lower in Lindahl equilibrium. In another paper (1973), Bergstrom has shown that if mean income in a community exceeds median income, if $-\epsilon/\delta>1$ and $\xi<-\xi/\delta$, the tax share of the citizen with median income will be lower in Lindahl equilibrium than in Bowen equilibrium. Our estimates suggest that each of these assumptions is likely to hold. It then follows that in the communities we observe, less than the Lindahl equilibrium quantity is provided. One could argue that this result provides some evidence to support John Kenneth Galbraith's contention that in reaching a "truce on income distribution" communities arrive at a quantity of public goods which is less than optimal. On the other hand, our estimates of income elasticities of less than unity for general municipal expenditures would seem "anti-Galbraithian."[16]

Our results suggest that the crowding parameter γ generally has a value of one or greater for cities with populations between 10,000 and 150,000. One could interpret this to mean that as the size of municipalities increases, the advantages of sharing the cost of public services among more persons are countervailed by the costs of sharing the services among more persons. An alternative statement of this proposition would be that over the range of city sizes which we studied, there appear to be no economies of scale to larger municipalities in the provision of public goods. It should, of course, be understood that this statement says nothing about the question of whether there are economies of scale to production of publicly supplied goods measured in some choice of physical units, but relates only to net effects of city size after crowding phenomena are accounted for.

One might reasonably ask why, if there are not increasing returns in the municipal provision of the goods and services which we study, is their provision in the public domain. The answer may be that there are substantial scale economies in the collective provision of these commodities

[15] Where some of the burdens of taxes and benefits of public goods are shared by noncitizens, we might choose to define Lindahl equilibrium in a municipality either as a situation in which there is agreement among all citizens or among all interested parties. If we take the former approach, Lindahl equilibrium is not necessarily Pareto optimal from the viewpoint of the national economy. Even here, one would expect that competition among municipalities for local industry would tend to result in efficient provision of public services. In any case, Lindahl equilibrium does require that there be agreement among citizens of all incomes. Thus, the requirements for income elasticities of tax shares remain unaltered.

[16] Galbraith's position, however, rests at least in part on the claim that expressed demands are a distortion of underlying "true" preferences since greater advertising of private goods reduces relative expressed demands. Hence he might choose to deny any normative significance for the demand functions which we estimate.

for units of smaller size than the cities which we consider.[17] This could provide sufficient reason that they be collectively provided. It may be that once some critical size is achieved, city size becomes largely a matter of indifference from an efficiency viewpoint over a fairly large range of sizes. Some corroborating evidence is provided by the fact that in metropolitan areas, contiguous municipalities frequently differ substantially and seemingly arbitrarily in size.

Appendix

Part I: Individual Errors of Perception

We introduce three lemmas, the first two of which were proved by Mosteller.

LEMMA 1: *If a random sample of size n is drawn from a probability distribution, f, which is continuous and nonvanishing in a neighborhood of its median, $\tilde{X}$, then the sample median $\hat{X}(n)$ is asymptotically normally distributed (as n becomes large) with expected value $\tilde{X}$ and variance $\sigma^2(n)=1/(4n[f(\tilde{X})]^2)$ where $\text{limit}_{n\to\infty}\ \sigma^2(n)=0$.*

LEMMA 2: *Let the random variable $\theta(n)$ be a function of the values $X_1, \ldots, X_n$ in a random sample of size n drawn from a probability distribution f. If $\theta(n)$ is asymptotically normally distributed and $\lim_{n\to\infty}\ [E\theta(n)]=\bar{\theta}$ where the asymptotic variance of $\theta(n)$ is zero, then if*

$$g[\theta(n)]$$

is a continuous real-valued function with a nonvanishing derivative in a neighborhood of $\bar{\theta}$, $g[\theta(n)]$ is an asymptotically normally distributed random variable such that

$$\lim_{n\to\infty} E[g(\theta(n))] = g(\bar{\theta})$$

and the asymptotic variance of g is zero.

[17] In the case of municipal courts and some policing functions it might be argued that these are social reasons for public provision quite distinct from economies of scale.

LEMMA 3: *If $X_1, \ldots, X_n, Y_1, \ldots, Y_n$ are symmetrically distributed and mutually independent random variables and if $Z_i=X_i+Y_i$ for $i=1, \ldots, n$, then $E(\hat{Z})=E(\hat{X})+E(\hat{Y})$ where $\hat{}$ denotes the sample median of a random variable.*

PROOF:

Since X, Y, and Z are symmetrically distributed, if we let a bar denote the sample mean, then

$$E(\hat{Z})=E(\overline{Z})=E(\overline{X})+E(\overline{Y})=E(\hat{X})+E(\hat{Y})$$

THEOREM: *In a municipality with n citizens, let the demand of consumer i with income Y_i for a public good be a random variable*

$$D_i = c[\tau^*(Y_i)]^{\delta}Y_i^{\epsilon}$$

Let

$$\tau(Y_i) = tY_i^{\xi}$$

be the "true" tax share and $\tau^*(Y_i)=Z_i\tau(Y_i)$ be his perceived tax share where Z_i is a random variable. Suppose that the values of Y and Z for the population of the city are determined by a random sample of size n drawn from a population in which $\log Z$ and $\log Y$ are independently and symmetrically distributed and where $E(\log Z)=0$ and $E(\log Y)=\log \hat{Y}$ where $\hat{Y}$ is the observed median income in the municipality. Then if $\hat{D}$ is the median quantity demanded by citizens of the municipality, $\log \hat{D}=\log c+\delta \log \tau(\hat{Y})+\epsilon \log \hat{Y}+\gamma$ where γ is asymptotically normally distributed with mean of zero and asymptotic standard deviation equal to zero.

PROOF:

From the demand equation we have,

$$\log D_i = (\delta\xi + \epsilon) \log Y_i + \delta \log Z_i$$

Applying Lemma 3, we have

$$E(\widehat{\log D}) = E[(\delta\xi + \epsilon) \log Y] + E(\widehat{\delta \log Z}) + \log c$$

where the hat denotes the sample median. But for any monotonic function f, $\widehat{f(x)}=f(\hat{x})$.

Hence,

$$E(\log \hat{D}) = E[(\delta\xi + \epsilon) \log \hat{Y}) + E(\delta \log \hat{Z}) + \log c$$

Lemma 2 implies that

$$\lim_{n\to\infty} E(\log \hat{D}) = (\delta\xi + \epsilon) \log [\lim_{n\to\infty} E(\hat{Y})] + \log [\lim_{n\to\infty} E(\hat{Z})] + \log c$$

Applying Lemma 1 and our assumptions about the distributions of Y and Z, we have

$$\lim_{n\to\infty} E(\log \hat{D}) = (\delta\xi + \epsilon) \log \hat{Y} + \log c = \log c + \delta \log \tau(\hat{Y}) + \epsilon \log \hat{Y}$$

By Lemma 1, the asymptotic variance of $\log \hat{D}$ is zero. The theorem follows immediately.

This result provides us with a partial justification for presuming that individual errors of perception will have no statistically unpleasant effects if the population is very large. Two problems remain. The Theorem assumes that $\log Y$ is symmetrically distributed. If this is not the case, then Lemma 3 does not apply and $\epsilon \log \hat{Y} + \delta \log \tau(\hat{Y}) + \log c$ may be a biased estimate of $\log \hat{D}$. This would not be a severe problem unless the asymmetry is substantial and highly variable from city to city. If, for example, income distributions are proportional between cities (as defined in the text) then the income distribution functions in different cities are simply translations of each other. In this case, the bias is the same for each city. The bias would affect the regression intercept but not the estimates of elasticities.

It also should be demonstrated that for cities as large as those which we consider, the asymptotic results are closely approximated. To find the magnitudes of these effects we can use the result that the variance of the median of a random sample of size n drawn from a normal distribution with variance σ^2 will be no larger than $(1/n)(2/\pi)\sigma^2$. (See J. Hodges and E. Lehmann.) If we postulate reasonable values for our parameters, for a community of 2,000 or more families, even very substantial variances of individual perception error result in a variance of the error term σ discussed above which would have negligible statistical effects.

It might also be noted that it is well that these error terms tend to be small, because they are not "well-behaved" in other ways. Although when the error is that of the actor rather than the observer it may be reasonable to assume that the error term is uncorrelated with the observed value of the variable (unlike the usual assumption when the error is that of the observer), it remains the case that the variance of the error term is likely to be smaller as city size increases. This violates the classical assumptions.

Part II: Proof of Theorem 1

For each $i \in M$ and $j = 1, \ldots, n$, let I_j^i be the closed interval between the maximum and the minimum income in p_j^i. We make the following continuity assumption. (C) For every $i \in M$, the set $\bigcup_{j=1}^n I_j^i$ is a closed interval, and the functions F_j^i, $j = 1, \ldots, n$, are all continuous and strictly increasing on I_j^i.

The cumulative income distribution, F^i, for the entire population P^i is easily seen to be

$$F^i = \sum_{j=1}^n \lambda_j^i F_j^i$$

Assumption C insures that F^i is continuous and strictly increasing on $\bigcup_{j=1}^n I_j$. If this assumption were dispensed with, one could prove a result similar to Theorem 1 which applies to discrete distributions. However, for our purposes, the added realism does not appear to justify the added tedium in the statement and proof of the theorem.

Let $\hat{Y}^i$ be the median income for the population P^i. Then

$$1/2 = F^i(\hat{Y}^i) = \sum_{j=1}^n \lambda_j^i F_j^i(\hat{Y}^i) = \sum_{j=1}^n \lambda_j^i F_j(k_i \hat{Y}^i)$$

It follows that the value of $(\lambda_1^i, \ldots, \lambda_n^i)$ determines $k_i \hat{Y}^i$. In fact since F^i is continuous and strictly increasing on $\bigcup_{j=1}^n I_j^i$, there is a continuous function g such that

$$k_i\hat{Y}^i = g(\lambda_1^i, \ldots, \lambda_n^i)$$

Since $\epsilon+\xi\delta\neq 0$, one can choose for each $i\in M$ and for $j=1, \ldots, n$, a $\tilde{Y}_j^i$ such that if $\hat{E}^i$ is the median quantity demanded in city i,

then

$$\hat{E}^i = c_j f(X^i)(t^i t_j)^\delta [\tilde{Y}_j^i]^{\epsilon+\xi\delta}$$

Thus for $j=1, \ldots n$, $\tilde{Y}_j^i = \rho_j \tilde{Y}_1^i$

where

$$\rho_j = \left[\frac{c_j t_j^\delta}{c_1 t_1^\delta}\right]^{1/(\epsilon+\xi\delta)}$$

Since E is the median quantity demanded, it must be that

$$1/2 = \sum_{j=1}^{n} \lambda_j^i F_j^i(\tilde{Y}_j^i) = \sum_{j=1}^{n} \lambda_j^i F_j^i(\rho_j \tilde{Y}_1^i)$$
$$= \sum_{j=1}^{n} \lambda_j^i F_j(k_i \rho_j \tilde{Y}_1^i)$$
$$= \sum_{j=1}^{n} \lambda_j^i F_j(g(\lambda_1^i, \ldots \lambda_n^i)\rho_j \frac{\tilde{Y}_1^i}{\hat{Y}^i}$$

The latter expression is a continuous strictly increasing function of $\tilde{Y}_1^i/\hat{Y}^i$. It follows that $\tilde{Y}_1^i/\hat{Y}^i$ is determined by the vector $(\lambda_1^i, \ldots \lambda_n^i)$. In fact, there is a continuous function h such that

$$h(\lambda_1^i, \ldots \lambda_n^i) = \left[\frac{\tilde{Y}_1^i}{\hat{Y}^i}\right]^{\epsilon+\xi\delta}$$

But

$$\hat{E}^i = c_1 f(X^i)(t^i t_1)^\delta \tilde{Y}_1^{i\epsilon+\xi\delta}$$
$$= h(\lambda_1^i, \ldots, \lambda_n^i) c_1 f(X^i)(\tau_1^i)^\delta (\hat{Y}^i)^\epsilon$$

Intermediate Products and the Pure Theory of International Trade: A Neo-Heckscher-Ohlin Framework

By RAVEENDRA N. BATRA AND FRANCISCO R. CASAS*

Economists in general and trade theorists in particular have now come to recognize the importance of intermediate inputs, not merely of primary factors, in the process of production. This is well reflected in the recent studies by Jaroslav Vanek, James Melvin (1969), and Roy Ruffin, among others. The main feature of these models, with the singular exception of Ruffin's, is their treatment of two commodities—traditionally taken to be consumption goods—as both final outputs and intermediate inputs for each other.[1] With such a minor difference, it is not surprising to find that the traditional theorems by T. Rybczynski, Wolfgang Stolper and Paul Samuelson, Eli Heckscher and Bertil Ohlin, etc., hold without any additional qualification in Vanek's model where the final goods also serve as intermediate products. Most of these traditional theorems depend crucially upon the factor-intensity ranking of the traded commodities, and as long as this ranking remains unaltered, as it does in Vanek's interindustry flows framework, these theorems will be valid in spite of the introduction of intermediate products.

Citing Vanek's results, Murray Kemp (1969) has defended the neglect of intermediate products in the earlier trade theory. In this paper, however, we intend to show that most of the traditional trade theorems may not hold without additional provisions if such intermediate products are introduced in the model as are produced solely to serve as inputs in the production of final goods. These we shall term *pure* intermediate products in order to distinguish them from the interindustry flows. Furthermore, in a two-good model where intermediate and final products are identical, one cannot explain the basis of trade in intermediate goods. For this reason, there exists no theory at present which would explain why trade occurs in such goods even though, as Paul Yates has shown, the bulk of international trade is in intermediate products—produced goods, like raw materials, spare parts, etc. which are solely used as inputs in the production of other products. Another purpose of this paper is thus to fill this gap and provide a theory explaining the basis of trade in intermediate products. In the traditional two final commodity trade

* Associate professor of economics, Southern Methodist University, and assistant professor, University of Toronto, respectively. An earlier draft of this paper was presented at the winter meetings of the Econometric Society, New Orleans, December 1971. The paper has benefited so much from the valuable suggestions of Jagdish Bhagwati, George Borts, James Melvin, C. Kuo, an unknown referee, and several participants in the trade session at the Econometric Society meetings and the International Economics Workshop at the University of Western Ontario, that the complexion and style of the present version bear little resemblance with those of the original draft. We gratefully acknowledge the generous suggestions offered by these economists; however, none of them is to be held responsible for any remaining errors. Batra's research was financed by a research grant from the Canada Council.

[1] For other studies which treat intermediate goods identically as final goods, see Paul Samuelson, Ronald McKinnon, Francisco Casas (1972a), and Robert Warne. On the other hand, Chulsoon Khang has analyzed a dynamic model of trade between one final good and an intermediate good.

model, we introduce a third good which is produced by primary factors only to serve as an input in the other two commodities. Such a model has been recently developed by Batra and Ranjit Singh to examine the growth behavior of a two-sector economy.

The discussion will evolve as follows. In Section I we give a complete description of the model. The Rybczynski theorem is then discussed in Section II, while Section III is concerned with the Stolper-Samuelson theorem. Finally, Section IV investigates the validity of the Heckscher-Ohlin theorem.

I. The Model with Intermediate Products

It is assumed that the economy consists of three commodities, two final products (X_1 and X_2), and one intermediate good (X_3) which is produced solely to serve as an input in the production of the final products. There are two primary factors of production, capital (K) and labor (L) which enter into the production process of all three commodities, and remain fully employed. Production functions exhibit constant returns to scale and diminishing returns to factor proportions. Perfect competition in product and factor markets, inelastic factor supplies, perfect factor mobility and factor price flexibility, and nonreversibility of factor intensities at all factor-price ratios are also assumed.

The assumption of full employment of primary factors implies that

$$(1) \qquad C_{L1}X_1 + C_{L2}X_2 + C_{L3}X_3 = \overline{L}$$

$$(2) \qquad C_{K1}X_1 + C_{K2}X_2 + C_{K3}X_3 = \overline{K}$$

where X_i denotes the output of the ith industry, $\overline{L}$ and $\overline{K}$ the fixed supplies of primary factors, and C_{Li} and C_{Ki}, respectively, the labor-output and capital-output ratios in the ith productive sector ($i=1, 2, 3$).

Let a_i denote the requirement of the material input, X_3, per unit of the ith final commodity, that is, $a_i = X_{3i}/X_i$. Following Samuelson, Vanek, and others who have worked with input-output models, a_i will be assumed to be constant. Furthermore, from our assumption that X_3 is used only as an input for the two final goods,

$$(3) \qquad X_3 = D_3 = a_1X_1 + a_2X_2$$

where D_3 is the demand for the intermediate product.

Turning now to the pricing of goods and factors, it is readily seen that with perfect competition in all markets and with constant returns to scale, the price of each commodity equals the sum of factor payments per unit of output, that is,

$$(4) \qquad C_{L1}w + C_{K1}r + a_1p_3 = p_1$$

$$(5) \qquad C_{L2}w + C_{K2}r + a_2p_3 = p_2$$

$$(6) \qquad C_{L3}w + C_{K3}r = p_3$$

where w and r denote, respectively, the wage rate and the rental on capital, and p_i is the price of the ith commodity. For the sake of simplicity, we shall assume hereafter that X_1 is the numeraire, so that $p_1 = 1$, and p_2 and p_3 will denote, respectively, the relative price of X_2 and X_3 in terms of X_1.

To complete the supply side of the model, we need only explain the determination of the various production coefficients. As stated earlier, the intermediate input-output coefficients, a_i, are assumed constant. As far as the labor-output and capital-output coefficients are concerned, they depend on factor prices. In particular, if σ_i is the elasticity of substitution between labor and capital in the ith sector, i.e., if $\sigma_i = [d(K_i/L_i)/d(w/r)] \cdot [(w/r)/(K_i/L_i)]$, then with linearly homogeneous production functions we may write

$$(7) \qquad \sigma_i = \frac{\dfrac{dC_{Ki}}{C_{Ki}} - \dfrac{dC_{Li}}{C_{Li}}}{\dfrac{dw}{w} - \dfrac{dr}{r}} \qquad (i = 1, 2, 3)$$

From our assumption of quasi concavity of the production functions, $\sigma_i > 0$.

A. *Geometrical Derivation of the Transformation Curve*

The principal issues in this section concern the shape and the slope of the transformation curve, defined as the locus of all efficient combinations of the final commodities satisfying two conditions, namely, i) the full employment of the primary factors, and ii) $D_3 = X_3$. Since there are actually three commodities produced and three factors (two primary inputs and one pure intermediate good), the derivation of the economy's transformation curve in our model is more complicated than in the traditional two-commodity, two-primary-factor model. Our first task will thus be that of deriving the locus of efficient outputs.

Here a distinction must be drawn between the gross and the net transformation curves. For expository purposes, assume that all three goods are produced only with the help of the two primary factors. We can then obtain a smooth, concave to the origin, "ruled" production possibility surface such as ABC in Figure 1. In each coordinate plane, the set of possible production points constitutes a gross transformation curve for the two relevant commodities.[2] For example, AB is the locus of all feasible combinations of X_1 and X_2 if no X_3 is produced, so that AB may be regarded as the gross transformation curve in our model.

Assume now that the production of X_2 requires the use of the intermediate good, X_3, in the proportion a_2 (i.e., $(X_{32}/X_2 = a_2)$. The maximum net output of X_2 must obviously be smaller than OB. Draw the line OD in the X_2X_3 plane such that the

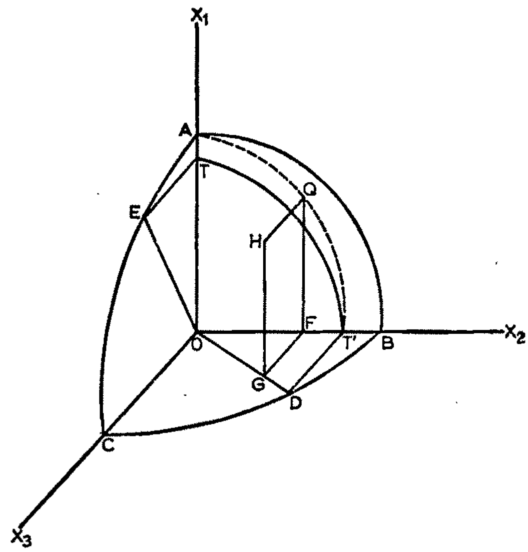

FIGURE 1

slope of OD with respect to the X_2 axis equals the given a_2; that is, $(DT'/OT') = a_2$. The maximum net output of X_2 is then seen to be OT', which utilizes DT' of the intermediate good, X_3, where D, being a point on the production surface, is both feasible and efficient.

Assume now that the net output of X_2 is actually OF, where OF is any arbitrary level of X_2 less than OT'. The amount of X_3 needed to produce this output level is given by FG. Since G does not lie on the production surface, the unemployed primary factors can be used in the production of the first commodity in an amount given by the vertical distance GH, from G to the production surface. By drawing HQ parallel to FG we obtain point Q in the X_1X_2 plane, which shows that with full employment of the two primary factors and a net output of X_2 equal to OF, the maximum net output of X_1 is $FQ(=GH)$. By repeating this construction for all possible net outputs of X_2 we may derive AT', which is the net transformation curve drawn under the assumption that $a_2 > 0$ and $a_1 = 0$.

The next step is to allow for the use of the intermediate input in the production of

[2] For further details on the derivation and construction of the production possibility surface in a model with three goods and two primary factors, see Melvin (1968).

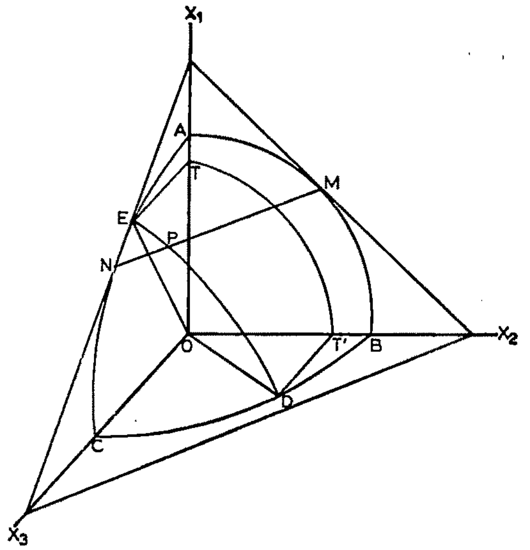

FIGURE 2

X_1 also. Let the slope of the line OE, with respect to the X_1 axis in the X_1X_3 plane, equal the given level of a_1 (i.e.,$ET/OT = a_1$); OT is then the maximum net output of X_1. By using the same procedure through which AT' was derived, given AB as the gross transformation curve, we can now obtain TT', given AT'. The curve TT' is then the net transformation curve for the economy.

Before proceeding to a rigorous analysis of the slope and the shape of this production possibility locus, a geometrical proof of the convexity of the production set will be given with the use of Figure 2, which reproduces the main features of Figure 1. The satisfaction of the full employment condition requires all efficient production points to be on the ABC surface. On the other hand, the condition that the demand for the intermediate product equals its supply requires that output combinations satisfy the equation

$$a_1X_1 + a_2X_2 = X_3 \tag{3}$$

Thus, any feasible and efficient point must lie on the interesection of the production surface and the plane given by equation (3). Melvin (1968) has shown that the production set in a three-good, two-primary-factor model is convex when production functions exhibit constant returns to scale. The intersection of such a set and a plane must therefore itself be convex—this intersection being the area OED in Figure 2. Thus, the curve ED is concave to the origin, and its projection on the X_1X_2 plane, the curve TT', must also be concave to the origin.

Figure 2 also illustrates the difference between the three-final-commodity model and the one described here with respect to the indeterminacy of output levels for given commodity prices. As Melvin (1968) has shown, any price plane will be tangent to the ABC surface along a line, such as MN. In our model, however, only point P along MN is relevant, because P is the only output combination satisfying (3). The latter constraint constitutes, in effect, a "demand" condition which solves the indeterminacy problem.

B. *The Slope and the Shape of the Transformation Curve*

The intuitive explanation concerning the shape of the transformation curve and the indeterminacy problem presented above may now be supplemented by a rigorous proof. However, the first step consists in obtaining an expression for the slope of the transformation curve. It has been shown by Vanek that the slope of the net transformation curve equals the negative of the commodity-price ratio even if the final commodities also serve as intermediate inputs. We will now show that this result holds in our model where the material input is not identical with the final goods.

Since national income may be measured as the value of final outputs or the sum of payments to primary factors, we can write

$$Y = X_1 + p_2X_2 = w\overline{L} + r\overline{K} \tag{8}$$

Differentiating this expression, keeping in mind that factor supplies are given, we obtain

$$(9)\quad dX_1 + p_2 dX_2 + X_2 dp_2 = \bar{L}dw + \bar{K}dr$$

Substituting for $\bar{L}$ and $\bar{K}$ from (1) and (2), we have

$$\begin{aligned}(10)\quad &\bar{L}dw+\bar{K}dr\\ &=(C_{L1}X_1+C_{L2}X_2+C_{L3}X_3)dw\\ &\qquad +(C_{K1}X_1+C_{K2}X_2+C_{K3}X_3)dr\\ &=(C_{L1}dw+C_{K1}dr)X_1\\ &\qquad +(C_{L2}dw+C_{K2}dr)X_2\\ &\qquad +(C_{L3}dw+C_{K3}dr)X_3\end{aligned}$$

Totally differentiating the price equations (4)–(6), and remembering that $dp_1=0$, we obtain

$$\begin{aligned}(11)\quad & C_{L1}dw + C_{K1}dr + a_1 dp_3 = \quad - (wdC_{L1} + rdC_{K1})\\ (12)\quad & C_{L2}dw + C_{K2}dr + a_2 dp_3 = dp_2 - (wdC_{L2} + rdC_{K2})\\ (13)\quad & C_{L3}dw + C_{K3}dr = dp_3 - (wdC_{L3} + rdC_{K3})\end{aligned}$$

It must be noted, however, that the equilibrium minimum-unit-cost condition of equality between the marginal rate of substitution among two factors and the ratio of these factors' prices implies that

$$(14)\quad wdC_{Li} + rdC_{Ki} = 0 \qquad (i = 1, 2, 3)$$

Using (14) and substituting (11)–(13) into (10) then yields

$$\begin{aligned}(15)\quad &\bar{L}dw+\bar{K}dr\\ &=-a_1X_1dp_3+X_2(dp_2-a_2dp_3)+X_3dp_3\\ &=-(a_1X_1+a_2X_2)dp_3+X_2dp_2+X_3dp_3\\ &=X_2dp_2\end{aligned}$$

From (9) and (15), we now obtain

$$(16)\quad dX_1 + p_2 dX_2 = 0$$

or

$$(16^*)\quad \frac{dX_1}{dX_2} = - p_2$$

which establishes the traditional result that the marginal rate of transformation between the final commodities equals the ratio of their prices (since $p_1=1$) in equilibrium.

Given the relationship expressed in (16*), the shape of the transformation curve can now be derived from the response of outputs to changes in their prices. In particular, if the output of a commodity rises in response to an increase in its relative price, and conversely, the net transformation curve is concave to the origin. Otherwise, it is convex to the origin.[3] Therefore, our task here is to find out the effect of a change in p_2 on the output of X_1 and X_2.

Solving (11)–(13) simultaneously for dw and dr, we obtain

$$(17)\quad dw = \frac{(C_{K1} + a_1 C_{K3})}{A}\, dp_2$$

$$(18)\quad dr = \frac{-(C_{L1} + a_1 C_{L3})}{A}\, dp_2$$

where

$$\begin{aligned}A &= C_{L1}C_{L2}(k_1 - k_2) + a_1 C_{L2}C_{L3}(k_3 - k_2)\\ &\qquad + a_2 C_{L1}C_{L3}(k_1 - k_3)\end{aligned}$$

and $k_i=K_i/L_i=C_{Ki}/C_{Li}$ is the capital-labor ratio in the ith industry.

We may now differentiate the full employment equations (1)–(3), keeping in mind that $\bar{L}$ and $\bar{K}$ are given, to obtain

$$(19)\quad C_{L1}dX_1 + C_{L2}dX_2 + C_{L3}dX_3 =$$

[3] However, if $dX_1/dX_2 \neq -p_2$ the shape of the transformation curve is not dependent exclusively on the response of outputs to changes in commodity prices. For example, Bhagwati and T. Srinivasan, Kemp and H. Herberg, and Ronald Jones (1971) have shown that in the presence of an interindustry wage differential, the transformation curve may be locally or globally convex to the origin even if the output responses to price changes are normal, and vice versa.

$$= -(X_1 dC_{L1} + X_2 dC_{L2} + X_3 dC_{L3})$$
$$= R_L\left(\frac{dw}{w} - \frac{dr}{r}\right)$$

$$(20)\quad C_{K1}dX_1 + C_{K2}dX_2 + C_{K3}dX_3$$
$$= -(X_1 dC_{K1} + X_2 dC_{K2} + X_3 dC_{K3})$$
$$= -R_K\left(\frac{dw}{w} - \frac{dr}{r}\right)$$

and

$$(21)\quad a_1 dX_1 + a_2 dX_2 - dX_3 = 0$$

where R_L and R_K are derived in the Appendix and are both positive. From (17) and (18), it is readily shown that

$$(22)\quad \left(\frac{dw}{w} - \frac{dr}{r}\right)$$
$$= \frac{(C_{K1}+a_1C_{K3})r+(C_{L1}+a_1C_{L3})w}{wr\cdot A}\,dp_2$$
$$= \frac{dp_2}{wr\cdot A}$$

since $C_{L3}w+C_{K3}r=p_3$ from (6) and $p_1=1$ by assumption.

We can now solve (19)–(21) simultaneously for dX_1 and dX_2, making use of (22), to derive:

$$(23)\quad \frac{dX_1}{dp_2} = \frac{-1}{wr\cdot A^2}\,[(C_{K2} + a_2C_{K3})R_L + (C_{L2} + a_2C_{L3})R_K]$$

$$(24)\quad \frac{dX_2}{dp_2} = \frac{1}{wr\cdot A^2}\,[(C_{K1} + a_1C_{K3})R_L + (C_{L1} + a_1C_{L3})R_K]$$

If the output responses to changes in commodity prices are to be "normal,"[4] then $dX_1/dp_2<0$ and $dX_2/dp_2>0$. From (23) and (24), it is clear that these inequalities are indeed satisfied in our model and, therefore, the output responses to a change in relative prices are normal, or equivalently, the net transformation curve is strictly concave to the origin. Witness further that (23) and (24) exhibit a monotonic relationship between the relative prices of the two final commodities and their outputs. This shows that there is only one configuration of commodity outputs consistent with one set of commodity prices. In other words, there is no indeterminacy problem present in our model.[5]

II. The Rybczynski Theorem

According to Rybczynski an increase in the supply of a primary factor of production promotes, at constant commodity prices, an expansion of the output of the commodity which uses the expanding factor relatively intensively at the expense of the output of the other commodity. We now explore the consequences of a rise in the supply of a factor for the output of the final goods, X_1 and X_2, in our model with intermediate products.[6] Now, if prices of final goods are kept constant ($dp_2=0$), the price of the intermediate good as well as the wage and rental rates remain constant,[7] so that the production coefficients will also remain unchanged. Differentiating (1)–(3) with respect to $\overline{K}$ and $\overline{L}$ then yields:

[4] By normal output response we mean that the supply curve for a final commodity has its usual positive slope.

[5] The need for an elaborate proof of the absence of an indeterminacy problem in our model arose from several questions raised by readers of an earlier draft of this paper. It may be emphasized here that even though our model is characterized by an inequality between the number of commodities and primary factors—an inequality whose implications for the indeterminacy problem have been thoroughly analyzed by Melvin (1968)—yet the model is completely determinate because the output of the third commodity, which serves as an intermediate input, is determined by the output of the two final commodities. Thus, in a sense, our model comprises three commodities and three inputs.

[6] For other extensions of the Rybczynski theorem, see Batra (1970), Kemp (1969), Jones (1968), and Casas (1972b).

[7] For a rigorous proof of the relationship between the prices of final goods and that of the intermediate product, see Section IV on the pattern of trade.

$$(25)\qquad \frac{\partial X_1}{\partial K} = \frac{(C_{L2} + a_2C_{L3})}{A}$$

$$(26)\qquad \frac{\partial X_2}{\partial K} = \frac{-(C_{L1} + a_1C_{L3})}{A}$$

$$(27)\qquad \frac{\partial X_3}{\partial K} = \frac{(a_1C_{L2} - a_2C_{L1})}{A}$$

$$(28)\qquad \frac{\partial X_1}{\partial L} = \frac{-(C_{K2} + a_2C_{K3})}{A}$$

$$(29)\qquad \frac{\partial X_2}{\partial L} = \frac{(C_{K1} + a_1C_{K3})}{A}$$

$$(30)\qquad \frac{\partial X_3}{\partial L} = \frac{(a_2C_{K1} - a_1C_{K2})}{A}$$

where, as before,

$$A = C_{L1}C_{L2}(k_1 - k_2) + a_1C_{L2}C_{L3}(k_3 - k_2) + a_2C_{L1}C_{L3}(k_1 - k_3)$$

It may be observed that the numerators of (25) and (29) are positive, and those of (26) and (28) are negative, so that the signs of $\partial X_i/\partial K$ and $\partial X_i/\partial L$ $(i=1, 2)$ depend on the sign of A. Examination of the latter reveals that if k_3 lies between k_1 and k_2, then A has a definite sign. In particular, if $k_1 \gtrless k_3 \gtrless k_2$. $A \gtrless 0$, so that $\partial X_1/\partial K \gtrless 0$, $\partial X_2/\partial K \lessgtr 0$, $\partial X_1/\partial L \lessgtr 0$, and $\partial X_2/\partial L \gtrless 0$.

THEOREM 1: *Thus, we may conclude that if the capital-labor ratio of the intermediate product lies in between the other two capital-labor ratios, the Rybczynski theorem holds: An increase in the stock of capital (labor), at constant prices, raises (lowers) the output of X_1 and lowers (raises) the output of X_2 if X_1 is capital-intensive relative to X_2, and vice versa.*

The effect of factor growth on the output of X_3 depends not only on the sign of A, but also on $a_i/C_{Li} = X_{3i}/L_i$ (in the case of capital accumulation) and $a_i/C_{Ki} = X_{3i}/K_i$ (in the case of growth of the labor force). Let us consider the case of an increase in the stock of capital. Then, if $A > 0$—so that the output of X_1 rises—$\partial X_3/\partial K \gtrless 0$ if $a_1/C_{L1} \gtrless a_2/C_{L2}$, and conversely if $A < 0$ and the output of X_2, instead of X_1, rises.

If k_3 does not lie between k_1 and k_2, then the Rybczynski theorem may not hold. If $a_1/C_{L1} = a_2/C_{L2}$, then $A = C_{L2}(C_{L1} + a_1C_{L3})(k_1 - k_1)$ and the theorem always holds. But this is a trivial case because, here, the output of X_3 is constant. The difficulty arises when $a_1/C_{L1} \neq a_2/C_{L2}$ and k_3 lies outside the confines of k_1 and k_2. There are two possibilities: (i) $k_1 \gtrless k_2 \gtrless k_3$ and (ii) $k_2 \gtrless k_1 \gtrless k_3$. It turns out that in case (i) the Rybczynski theorem holds if $a_2/C_{L2} > a_1/C_{L1}$, whereas in case (ii) its validity requires that $a_1/C_{L1} < a_2/C_{L2}$. Take, for example, the case where $k_1 > k_2 > k_3$. Here $(k_1 - k_2) > 0$ and if $a_2/C_{L2} > a_1/C_{L1}$, we can see that $a_1C_{L2}(k_2 - k_3) < a_2C_{L1}(k_1 - k_3)$ because $(k_1 - k_3) > (k_2 - k_3)$. Hence, $A > 0$, $\partial X_1/\partial K > 0$ and $\partial X_2/\partial K < 0$, $\partial X_1/\partial L < 0$ and $\partial X_2/\partial L > 0$. Therefore, the Rybczynski theorem is valid. This leads to the following conclusion:

THEOREM 2: *If a commodity is relatively intensive in the use of the intermediate good, and if the capital-labor ratio of that commodity lies between the capital-labor ratio of the intermediate product and that of the other final commodity, the Rybczynski theorem holds.*

In Theorem 2, intensity in the use of the intermediate good is measured by $a_i/C_{Li} = X_{3i}/L_i (i=1, 2)$.[8] It is evident that if the

[8] Alternatively, intensity in the use of the intermediate good can be expressed in terms of the intermediate input/capital ratio, $a_i/C_{Ki} = X_{3i}/K_i$. Thus, A may be rewritten as

$$A = C_{K1}C_{K2}\left(\frac{1}{k_2} - \frac{1}{k_1}\right) + a_1C_{K2}C_{K3}\left(\frac{1}{k_2} - \frac{1}{k_3}\right) + a_2C_{K1}C_{K3}\left(\frac{1}{k_3} - \frac{1}{k_1}\right)$$

If $k_1 > k_2 > k_3$, for example, a sufficient condition for $A > 0$ is that $a_2/C_{K2} > a_1/C_{K1}$. Hence, Theorem 2 remains unaffected by the change in the definition of intensity in the use of the intermediate good.

conditions implied in Theorem 2 are not satisfied, then the Rybczynski theorem may not hold.

What is the economic explanation of the fact that, unlike in Vanek's interindustry flows framework, the Rybczynski theorem may not be valid in our model which allows for the presence of pure intermediate goods? The answer to this question is facilitated by introducing a distinction between the net capital-labor ratio and the gross capital-labor ratios in the final products. The net or apparent capital-labor ratio of the ith final commodity is given by $k_i = K_i/L_i = C_{Ki}/C_{Li}$, whereas the gross or total capital-labor ratio, k_i^*, equals the ratio between the amounts of capital and labor utilized directly and indirectly by the ith final good. For example, the gross amount of capital employed by the ith final commodity, K_i^*, equals K_i plus the amount of capital employed in the intermediate good (i.e., K_3) multiplied by the proportion of the intermediate product used in the production of the ith final good, that is,

$$K_i^* = K_i + (X_{3i}/X_3)K_3$$

Similarly, the gross amount of labor utilized by the ith final good is given by

$$L_i^* = L_i + (X_{3i}/X_3)L_3$$

Hence,

$$k_i^* = \frac{K_i + (X_{3i}/X_3)K_3}{L_i + (X_{3i}/X_3)L_3} = \frac{k_iC_{Li} + a_ik_3C_{L3}}{C_{Li} + a_iC_{L3}} \qquad (i = 1, 2)$$

Thus, if the first commodity is apparently capital-intensive relative to the second commodity (that is, if $k_1 > k_2$), then it will be truly capital intensive (that is, $k_1^* > k_2^*$) only if

$$\frac{k_1C_{L1} + a_1k_3C_{L3}}{C_{L1} + a_1C_{L3}} > \frac{k_2C_{L2} + a_2k_3C_{L3}}{C_{L2} + a_2C_{L3}},$$

or

$$C_{L1}C_{L2}(k_1 - k_2) + a_1C_{L2}C_{L3}(k_3 - k_2) + a_2C_{L1}C_{L3}(k_1 - k_3) = A > 0$$

In other words, conditions which are sufficient to ensure that $A > 0$ will also ensure that the first commodity is relatively capital-intensive both in net and gross terms. We have previously established that $A > 0$ if (i) $k_1 > k_3 > k_2$, or (ii) $k_1 > k_2 > k_3$ *and* $a_2/C_{L2} \geq a_1/C_{L1}$. From this discussion the following general result is immediate:

The factor-intensity rankings of the final products in the net and gross sense are identical if (i) k_3 lies between k_1 and k_2, or (ii) the commodity whose capital-labor ratio lies between the capital-labor ratios of the intermediate product and the other final product is at least as intensive in the use of the intermediate product as the other final commodity. Any one of these conditions is also sufficient to give rise to an unambiguous sign of A.

If condition (ii) above is not satisfied there arises the possibility of a conflict between the factor-intensity rankings in the net and the gross sense; that is to say, a commodity may be relatively capital-intensive in the net sense, but relatively labor-intensive in the gross sense, and vice versa. This possibility of a conflict between the net and the gross factor-intensity rankings of the final products constitutes the basic difference between our model with pure intermediate products and Vanek's interindustry flows model. As shown originally by Vanek and recently by Casas (1972a) the gross and the net capital-labor ratios in the final products always enjoy the same ranking in a model where interindustry flows are present. In our model with pure intermediate products, however, the net or the apparent factor-intensity ranking of a final commodity may not reflect its true or gross factor-intensity ranking.

It must be clear by now that the Rybczynski theorem will be invalid only if the net and the gross factor-intensity rankings run counter to each other; in other words, a rise in the supply of, say, capital alone may lower the output of an apparently capital-intensive commodity at constant prices, if in the gross sense this commodity is relatively labor-intensive. Needless to say, the Rybczynski theorem is always valid if factor-intensity rankings are defined in the gross sense.

III. The Stolper-Samuelson Theorem

According to the Stolper-Samuelson theorem, a rise in the relative price of a commodity raises the real reward of the primary factor employed more intensively by it and lowers the real reward of the other primary factor, and conversely. We will now examine the implications of a change in the price ratio between the final products for factor rewards in our model incorporating intermediate goods.[9]

Let us assume that the relative price of the second commodity increases, i.e., $dp_2>0$; from (4)–(6) and (17)–(18) the change in real factor rewards in terms of the higher priced commodity is given by:

$$\frac{d(w/p_2)}{dp_2} = \frac{(C_{K2} + a_2C_{K3})}{p_2^2 \cdot A} \tag{31}$$

$$\frac{d(r/p_2)}{dp_2} = \frac{-(C_{L2} + a_2C_{L3})}{p_2^2 \cdot A} \tag{32}$$

For the Stolper-Samuelson theorem to hold, $d(w/p_2)/dp_2>0$ and $d(r/p_2)/dp_2<0$ if $k_1>k_2$, and vice versa. The numerator of (31) is positive and that of (32) is negative, so that the signs of $d(w/p_2)/dp_2$ and $d(r/p_2)/dp_2$ depend on the sign of A. In other words, the Stolper-Samuelson theorem holds if A has the same sign as (k_1-k_2) or, what is the same thing, if the net and gross factor-intensity rankings are identical; otherwise, the Stolper-Samuelson theorem may not hold.

Another result worth investigating is the so-called fundamental duality theorem. In terms of a two-commodity, two-factor model, Jones (1965) has shown that there exists a dual relationship between the Rybczynski theorem and the Stolper-Samuelson theorem in the sense that the effect of a change in factor endowments on commodity outputs at constant prices is identical to the effect of a change in commodity prices on nominal factor rewards at constant factor endowments. It is interesting to see that this duality remains unscathed in our generalized model where pure intermediate goods are allowed. This may be demonstrated simply by comparing (18) and (27) to find that

$$\frac{\partial X_2}{\partial K} = \frac{dr}{dp_2} = \frac{-(C_{L1} + a_1C_{L3})}{A} \tag{33}$$

IV. The Pattern of Trade

It is fashionable to attempt to explain the pattern of trade between two countries in terms of the Heckscher-Ohlin theorem: a country exports the commodity which uses intensively its relatively abundant factor, and imports the commodity which is intensive in the use of its relatively scarce factor. Traditionally, the logical validity of this theorem has been shown to depend crucially upon the validity of the Stolper-Samuelson and the Rybczynski theorems. Unfortunately, in our model where three goods are produced, the pattern of trade turns out to be indeterminate if all three goods are to be traded, even if the Rybczynski and the Stolper-Samuelson theorems hold unambiguously. To get an immediate idea of this problem, let us revert to the price equations (4)–(6). If all three goods are traded, p_1, p_2, and p_3 are all determined exogenously. The three equations (4)–(6) then contain three pa-

[9] For other extensions of the Stolper-Samuelson theorem, see Nobuo Minabe, Batra (1968), Kemp (1969) and Jones (1968).

rameters, p_1, p_2, and p_3, to solve for two unknowns w and r in terms of the input-output coefficients, so that the model becomes indeterminate.

One solution to this problem is to assume that world prices are such that the production of one commodity is unprofitable, so that it is no longer produced. But this is not attractive, for then we fall into the domain of the traditional two-good model. Another solution lies in the stipulation that one of the three goods is nontraded. For example, suppose the intermediate good is not traded at all. Then the three equations (4)–(6) containing two parameters p_1 and p_2 can be solved to obtain the three unknowns w, r, and p_3. The number of equations matches the number of unknowns, and the indeterminacy problem disappears.

A closely related, though not completely identical, question concerns the determination of the pattern of trade when all three goods are to enter trade. Suppose initially no trade in X_3 is allowed. If we assume that international production functions are identical, then the Heckscher-Ohlin theorem follows directly from the validity of the Stolper-Samuelson theorem. If, in addition, we assume that consumption patterns are also identical internationally, then the Heckscher-Ohlin theorem derives from the validity of the Rybczynski theorem. If all three goods continue to be produced in free trade equilibrium, factor prices are equated between countries; X_3 also commands the same price between countries, and there is no incentive to trade X_3 once the prohibition to such trade is lifted.

Nonetheless, trade *could* take place in either direction. World outputs and world demand for final products are unaffected, because the free trade equilibrium gives rise to a given set of world prices. But each country's transformation curve shifts—outwards for the country importing X_3 and inwards for the other. Suppose there are two countries, the home country and the foreign country, and suppose further that the former is relatively capital-abundant and that $k_1 > k_3 > k_2$. If X_3 is exported by the home country, at free trade prices the home production of both X_1 and X_2 declines (and rises abroad). Thus the home country might eventually import *both* X_1 and X_2 in exchange for X_3, although the Heckscher-Ohlin theory would require the home country to *export* X_1. Alternatively, if the home country imports X_3, it might (i) be an exporter of X_1 and an importer of X_2, or (ii) export both X_1 and X_2 and import X_3. Thus without further restrictions it is impossible to pick out *any* commodity and state whether it is imported or exported by the home country.

The solution that we wish to propose must have become obvious by now. If one of the three goods is nontraded, not only do we solve the indeterminacy problem in the model, but we can also salvage the Heckscher-Ohlin theory. Note that our solution does not require that the nontraded good be the intermediate good only, although, as it turns out, if the nontraded good is one of the final goods, the validity of the Heckscher-Ohlin theorem is not all that obvious.

Let us define the home country to be capital-abundant relative to the foreign country if

$$\omega_h > \omega_f$$

where $\omega = w/r$ is the wage-rental ratio and the subscripts h and f refer, respectively, to the home and foreign countries. If the intermediate good is not traded, all that we need to demonstrate in order to prove the Heckscher-Ohlin theorem is that $(d\omega/dp_2)$ has an unambiguous sign. From (17) and (18)

$$\text{(34)} \quad \frac{d\omega}{dp_2} = \left(r\frac{dw}{dp} - w\frac{dr}{dp}\right) \bigg/ r^2 = \frac{1}{r^2 A}$$

From (34) it is clear that the relationship between ω and p_2 is unique only if A has an unambiguous sign. If $A > 0$, then with $\omega_h > \omega_f$, it is clear that

$$p_{2h} > p_{2f}$$

where p_{2j} is the autarky relative price of the second good in terms of the first in the jth country ($j = h, f$). The home country will then export X_1 and import X_2. On the other hand, if $A < 0$, then with $\omega_h > \omega_f$,

$$p_{2h} < p_{2f},$$

so that the home country will export X_2 and import X_1. In general, with the intermediate good nontraded, the Heckscher-Ohlin theorem will hold if sign $(A) = $ sign $(k_1 - k_2)$ and we already know that a sufficient condition for this is that k_3 lies between k_1 and k_2.

Let us now consider the other case where one of the final goods is the nontraded good. Let X_1 be such a good. For the demonstration of the Heckscher-Ohlin theorem, we now need an expression relating p_3/p_2 with ω. From (13), (17), and (18) it is readily shown that

$$\text{(35)} \qquad \frac{dp_3}{dp_2} = \frac{C_{L1}C_{L3}(k_1 - k_3)}{A}$$

Dividing (35) by (34), we have

$$\text{(36)} \qquad \frac{dp_3}{d\omega} = r^2 C_{L1}C_{L3}(k_1 - k_3)$$

and from (34) and (36)

$$\text{(37)} \qquad \frac{d(p_3/p_2)}{d\omega} = \frac{1}{p_2^2}\left[p_2\frac{dp_3}{d\omega} - p_3\frac{dp_2}{d\omega}\right]$$
$$= \frac{r^2}{p_2^2}[(p_2 - a_2p_3)C_{L1}C_{L3}(k_1 - k_3) + p_3C_{L1}C_{L2}(k_2 - k_1) + a_1p_3C_{L2}C_{L3}(k_2 - k_3)]$$

If $\omega_h > \omega_f$ and $k_2 > k_3$, then from the Heckscher-Ohlin theorem we would expect the home country to export X_2 and import X_3. For this pattern of trade to take place, we require that

$$\frac{d(p_3/p_2)}{d\omega} > 0$$

so that $(p_3/p_2)_h > (p_3/p_2)_f$ when $\omega_h > \omega_f$. However, $k_2 > k_3$ alone is not sufficient to ensure this. A sufficient condition for $d(p_3/p_2)/d\omega > 0$ is that $k_2 > k_1 > k_3$, that is, X_2 is the most capital-intensive and X_3 the least capital-intensive of all three goods. Conversely, if $k_2 < k_3$, the validity of the Heckscher-Ohlin theory requires that $d(p_3/p_2)/d\omega < 0$, and this is sufficiently ensured if $k_2 < k_1 < k_3$.

A definite pattern emerges from our discussion concerning the validity of the Heckscher-Ohlin theorem when one of the goods is specified as being the nontraded good. This is summarized in the following theorem:

THEOREM 3: *If one of the goods is specified as being nontraded (whether it is a final or an intermediate good), the international exchange of the other two will follow the Heckscher-Ohlin dictum if the capital-labor ratio of the nontraded good lies between the capital-labor ratios of the other two goods.*

If this theorem is not satisfied, the Heckscher-Ohlin theorem may not hold even if one of the three goods is specified as the nontraded good.

The Nature of the Free Trade Equilibrium

Given that one commodity is nontraded, what is the nature of equilibrium in free trade? If the nontraded good is the intermediate product, the answer is very simple and conforms to the traditional graphical explanations, where the world prices in conjunction with the transformation curve determine the free trade production point, and where the consumption point is deter-

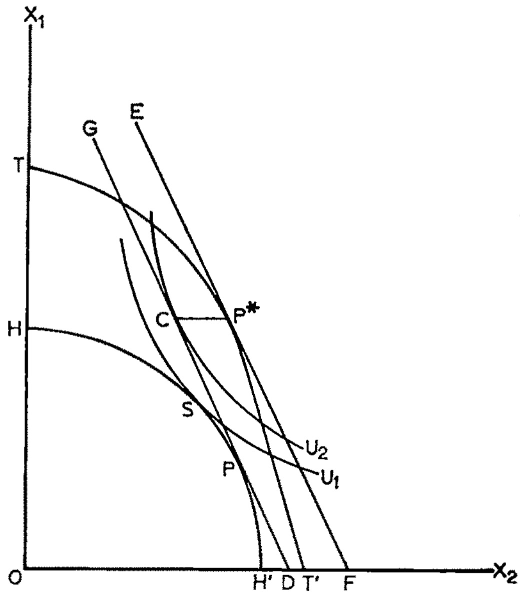

FIGURE 3

mined by the demand conditions. The problem is not so simple when the nontraded good is one of the final commodities. The free trade consumption point relating to final goods is, as before, determined by the demand conditions, but the production point is determined not only by world prices but also by the volume of trade.

As an illustration, consider Figure 3 which depicts the case of the home country exporting X_2 and importing X_3 while treating X_1 as the nontraded good. As previously seen, such a pattern would arise if $\omega_h > \omega_f$ under autarky and $k_2 > k_1 > k_3$. In Figure 3, HH' is the home country's net transformation curve and S is the point of self-sufficiency equilibrium which is determined by the tangency of the social indifference curve U_1 with HH'. Since the home country exports X_2 and imports X_3, the switch from autarky to free trade causes a rise in p_2 and a decline in p_3, with all prices expressed in terms of the nontraded good. For the time being assume that no X_3 is imported. Then the rise in p_2 as a result of the introduction of trade shifts production from S to P where GD, the price line prevailing in the free trade equilibrium, is tangent to the net transformation curve, and consumption moves from S to C which lies on a higher indifference curve U_2. The final equilibrium production point is not P, however, for the imports of X_3 will shift the transformation curve outwards, the extent of this shift depending upon the volume of X_3 imported. Such a transformation curve is given by TT' and the final production point is given by P^* where the price line EF, parallel to GD, touches the new transformation curve.

Several aspects deserve further exposition. First, the free trade equilibrium production point P^* is horizontally aligned with the consumption point C, showing that the supply of and the demand for X_1 are equal. Second, the output of X_2 corresponding to P^* may be smaller or larger than that corresponding to P. This follows from the fact that the import of X_3 is equivalent to the injection of capital and labor in the home country in the proportion $C_{K3}/C_{L3} = k_3$. However, with $k_2 > k_1 > k_3$, the imports of X_3 will result in a decline of the output of X_2 and a rise in the output of X_1 at the free trade prices if X_2 is capital-intensive in gross terms,[10] and vice versa. For this reason, if we assume that sign $(A) =$ sign $(k_1 - k_2)$, it follows that the shift in the transformation curve

[10] If we rewrite equation (3) as

$$X_3 = a_1 X_1 + a_2 X_2 - E_3$$

where E_3 denotes the imports of the intermediate good, then at constant prices and with fixed supplies of primary factors it is readily shown that

$$\frac{\partial X_1}{\partial E_3} = -\frac{C_{L2} C_{L3}(k_2 - k_3)}{A}$$

and

$$\frac{\partial X_2}{\partial E_3} = \frac{C_{L1} C_{L3}(k_1 - k_3)}{A}$$

Thus, $\partial X\ /\partial E_3 \gtrless 0$ and $\partial X_2/\partial E_3 \lesseqgtr 0$ if $A \lesseqgtr 0$.

from HH' to TT' will be biased towards X_1. Third, the length CP^* measures the value of the imports of X_3 in terms of the second commodity and, in equilibrium, this equals the value of the exports of X_2. This follows from the fact that the change in the value of home production, equal to CP^* in Figure 3, must be equal to the amount of the increase in the availability of the intermediate input multiplied by its price. Expressed in terms of the second commodity, this equals p_3E_3/p_2, where E_3 is the amount of X_3 imported, that is,[11]

$$CP^* = p_3E_3/p_2$$

But p_3E_3/p_2 is nothing but the value of the imports of E_3 expressed in terms of the second commodity. With balanced trade, this must equal the export of X_2 which, in Figure 3, is also given by CP^*. In other words, the location of the final production point P^* satisfies the balance of trade equilibrium condition, namely, $p_3E_3=p_2E_2$, where E_2 is the amount of X_2 exported. In toto, Figure 3 shows that as a result of the switch from autarky to free trade, production moves from S to P^*, consumption moves from S to C, and welfare improves from U_1 to U_2.

An analogous but opposite procedure can be followed for the case where the home country is an exporter of X_3 and an importer of X_2. Here, $k_2<k_1<k_3$ with $\omega_h>\omega_f$ under autarky. This case is pictured in Figure 4 where the switch from autarky to free trade takes production from S to P^*, consumption from S to C, and welfare from U_1 to U_2. The distance CP^* equals the imports of X_2 as well as the value of the exports of X_3 expressed in terms of the second commodity, with the demand for X_1 equal to the domestic production of X_1.

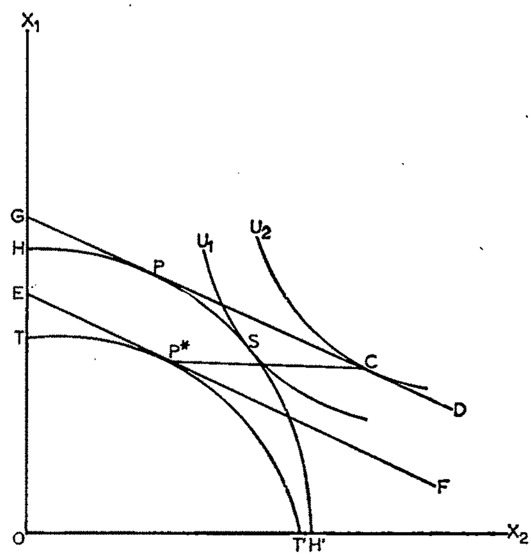

FIGURE 4

[11] At constant prices, the increase in the total value of domestic output resulting from the importation of E_3 units of the intermediate good is given by

$$\left(\frac{\partial X_1}{\partial E_3} + p_2\frac{\partial X_2}{\partial E_3}\right) E_3$$

This is easily shown to equal p_3E_3 in terms of the first commodity and, hence, p_3E_3/p_2 in terms of the second good.

APPENDIX

From the definition of σ_i (equation (7)), the minimum-unit-cost conditions (equation (14)), and the price equations (4)–(6), the following results may be derived:

$$\frac{dC_{K1}}{C_{K1}} = \sigma_1\left(\frac{dw}{w} - \frac{dr}{r}\right) + \frac{dC_{L1}}{C_{L1}}$$

$$= \sigma_1\left(\frac{dw}{w} - \frac{dr}{r}\right) - \frac{r}{w}\,\frac{dC_{K1}}{C_{L1}}$$

Hence,

$$\frac{dC_{K1}}{wC_{L1}C_{K1}}(wC_{L1} + rC_{K1}) = \sigma_1\left(\frac{dw}{w} - \frac{dr}{r}\right)$$

or

$$dC_{K1} = \frac{wC_{L1}C_{K1}\sigma_1}{(1 - a_1p_3)}\left(\frac{dw}{w} - \frac{dr}{r}\right)$$

In a similar way, it is readily shown that

$$dC_{L1} = \frac{-rC_{L1}C_{K1}\sigma_1}{(1 - a_1p_3)}\left(\frac{dw}{w} - \frac{dr}{r}\right)$$

$$dC_{K2} = \frac{wC_{L2}C_{K2}\sigma_2}{(p_2 - a_2p_3)}\left(\frac{dw}{w} - \frac{dr}{r}\right)$$

$$dC_{L2} = \frac{-rC_{L2}C_{K2}\sigma_2}{(p_2 - a_2p_3)}\left(\frac{dw}{w} - \frac{dr}{r}\right)$$

$$dC_{K3} = wC_{L3}C_{K3}\sigma_3\left(\frac{dw}{w} - \frac{dr}{r}\right)$$

$$dC_{L3} = -rC_{L3}C_{K3}\sigma_3\left(\frac{dw}{w} - \frac{dr}{r}\right)$$

Using these relationships, we may now derive:

$$= \frac{-(X_1dC_{L1} + X_2dC_{L2} + X_3dC_{L3})}{\left(\frac{dw}{w} - \frac{dr}{r}\right)}$$

$$= r\left[\frac{X_1C_{L1}C_{K1}\sigma_1}{(1 - a_1p_3)} + \frac{X_2C_{L2}C_{K2}\sigma_2}{(p_2 - a_2p_3)} + X_3C_{L3}C_{K3}\sigma_3\right] > 0$$

and

$$R_K = \frac{(X_1dC_{K1} + X_2dC_{K2} + X_3dC_{K3})}{\left(\frac{dw}{w} - \frac{dr}{r}\right)}$$

$$= w\left[\frac{X_1C_{L1}C_{K1}\sigma_1}{(1 - a_1p_3)} + \frac{X_2C_{L2}C_{K2}\sigma_2}{(p_2 - a_2p_3)} + X_3C_{L3}C_{K3}\sigma_3\right] > 0$$

The "F-Twist" and the Methodology of Paul Samuelson

By STANLEY WONG*

That economics is in an uneasy state is now widely recognized.[1] Undoubtedly, remedies to rectify this situation will involve methodological considerations about the role and status of theories in economics. Most economists will dread this prospect; most methodological discussions in economics are vague and confusing debates, which are of little apparent significance to the day-to-day work of the practicing economist. Regrettably, to this category of methodological debates must be added the celebrated methodological dispute between two of the most distinguished economists, Milton Friedman and Paul Samuelson.

What then is the excuse to write yet another paper on methodology? The alternative to bad methodological discussion is not *no* methodological discussion. As Samuelson put it quite succinctly:

> . . . a scholar in economics who is fundamentally confused concerning the relationship of definition, tautology, logical implication, empirical hypothesis, and factual refutation may spend a lifetime shadow-boxing with reality. In a sense, therefore, in order to earn his daily bread as a fruitful contributor to knowledge, the practitioner of an intermediately hard science like economics must come to terms with methodological problems. [1965b, p. ix]

It is the purpose of this paper to show that no substantive issues were at stake in the Friedman-Samuelson dispute. Many, perhaps most, economists consider the debate to be over, with Samuelson's position upheld.[2] The importance of sorting out the issues cannot be overemphasized. The methodological position we adopt profoundly influences our theoretical work and our assessment of it.

Section I provides a summary of Friedman's methodological position; Section II, Samuelson's critique (the F-Twist) of Friedman's position. Section III discusses Friedman's view as an example of instrumentalism. Section IV provides a critique of Samuelson's critique. Section V examines Samuelson's view as an example of descriptivism and argues that it is untenable. Finally, Section VI argues that the methodological choice is not one between the Friedman view and the Samuelson view *but* between both views and the view that theories are explanatory and informative.

I. The Methodology of Milton Friedman

In his provocative essay, "The Methodology of Positive Economics," Friedman gives the only detailed account of his methodology.

Following John Neville Keynes' distinction of normative and positive economics, Friedman argues that the role of

* King's College, Cambridge, England. The first version was presented in June 1971 to Joan Robinson's Seminar at the Faculty of Economics and Politics, University of Cambridge. This paper has benefitted enormously from the strong encouragement and penetrating criticisms of Joan Robinson, Lawrence Boland, G. C. Harcourt, Luigi Pasinetti, Alan Millar, Ian McFetridge, Gordon Nagel, Victoria Becker and Edwin Wong. The Canada Council has generously supported the research which made this paper possible.

[1] See articles by Frank Hahn and Wassily Leontief. Moreover, Joan Robinson (1964) has for years deplored the poverty of contemporary economic theory.

[2] Compare articles by D. V. T. Bear and Daniel Orr, Jack Melitz, and Tjalling Koopmans. My observation is shared by Karl Brunner.

the economist qua economist is to do positive economics, the study of "what is" rather than of "what should be." The task of positive economics ". . . is to provide a system of generalizations that can be used to make correct predictions about the consequences of any change in circumstances. Its performance is to be judged by the precision, scope, and conformity with experience of the predictions it yields" (p. 4).

How is a theory to be evaluated? For Friedman a ". . . theory is to be judged by its predictive power of the class of phenomena which it is intended to 'explain' . . . the only relevant test of the *validity* of a hypothesis is comparison of its predictions with experience" (pp. 8–9).

What about the descriptive realism of the assumptions or of the theory? Friedman claims that it is not possible to achieve since the enumeration of details need not stop in a description. He says that if complete descriptive realism were possible, it would not be desirable since it would render the theory utterly useless, devoid of any predictive power (see p. 32).

He asserts that the only relevant question to ask is ". . . whether they are sufficiently good approximations for the purpose at hand. And this question can be answered only by seeing whether a theory works, which means whether it yields sufficiently accurate predictions. The two supposedly independent tests [test of the assumptions and test of the theory by a test of its predictions] thus reduce to one test" (p. 15).

II. The F-Twist Methodology

Sensing the possible reemergence of the doctrine of *apriorism*, which he has scornfully attacked on many occasions (1952, p. 62; 1965b, p. 3), Samuelson assails Friedman's methodological view for praising the shortcomings of a theory as its virtues. According to Samuelson, Friedman's methodological position can best be summarized as the F-Twist: "A theory is vindicable if (some of) its consequences are empirically valid to a useful degree of approximation; the (empirical) unrealism of the theory 'itself' or of its 'assumptions,' is quite irrelevant to its validity and worth" (1963, p. 232).[3]

Samuelson's critique of Friedman's methodological position depends on what he (Samuelson) considers to be the proper relationship between a theory, its assumptions, and its consequences. Accordingly, a somewhat detailed account of Samuelson's critique follows.

Samuelson defines a theory (called B) ". . . as a set of axioms, postulates, or hypotheses that stipulate something about observable reality" (1963, p. 233), i.e., the set is either refutable or confirmable in principle by observation.[4] A theory has a set of consequences (called C) which are logically implied by the theory and a set of assumptions (called A) which logically implies the theory.

"If C is the complete set of consequences of B, it is identical with B . . . " (p. 234), and if A is the minimal set of assumptions that give rise to B, then A is identical with B. According to Samuelson, if C and A are given the above interpretation, they are logically equivalent to B and hence to each other. Therefore the degree of "realism," "factual correctness," "empirical validity," or "truth" of any one of A, B, C is shared by the other two.

Samuelson contends that it is a contradiction to maintain that any one of A, B, C can have a degree of realism different from the other two. He cites as an example of this point, Hendrik Houthakker's result (1950) that the ordinal theory of utility is

[3] Obviously, there is ambiguity in the usage of such words as theory, assumptions, implications, consequences, etc. This has hindered clarification of the issue.

[4] Samuelson does not seem to be aware of the problems associated with confirmation. For illuminating discussions of these problems, see John Watkins (1957), (1960) and Nelson Goodman.

logically equivalent to the Strong Axiom of revealed preference, that is, a rational consumer in conventional ordinal utility theory never violates the Strong Axiom.

In case only some part of A, B, C has empirical validity, Samuelson gives the following argument.

Consider a proper subset (called $C-$) of the consequence set C and let set A be a proper subset of the enlarged assumption set (called $A+$). Symbolically, he represents this relationship as[5]

(1) $A+\supset A\equiv B\equiv C\supset C-$

If C has "... complete (or satisfactory) empirical validity" (p. 234), then so does the theory, B, and the assumption, A. However, we cannot say anything about $A+$ "... unless its full content, which we may call $A+\equiv B+\equiv C+$ also have empirical validity. If that part of $C+$ which is not in C is unrealistic in the sense of being empirically false at the required level of approximation, then $A+$ is definitely the worse for it" (p. 234). According to Samuelson, then, it is absurd to maintain that if only some parts of C are valid, then B and A are important though invalid. The only thing to do he says is to eliminate that part of B and A corresponding to the invalid part of C and retain $A-\equiv B-\equiv C-$.

We can summarize Samuelson's critique as follows. 1) It is a contradiction to maintain that all consequences can be valid and the theory and the assumptions not valid. 2) It is absurd to maintain, in the case where only some of the consequences are valid, that the theory and the assumptions are important though invalid. The part of the theory set and the assumption set corresponding to the invalid part of the consequence set should be eliminated. For convenience let us call 1) the F-Twist Theorem and 2) the F-Twist Corollary.

[5] The $\supset$ is ambiguously used by Samuelson. It is not clear whether it signifies class inclusion or implication

III. Instrumentalism and the Methodology of Milton Friedman

Instrumentalism is the thesis that a theory in science is merely an instrument for prediction of observable reality.[6] Accordingly, a theory cannot be properly called true or false. It is tested only by the conformity of its predictions with observable reality. It is superfluous and irrelevant to test assumptions as they are merely tools or instruments which are judged by their ease or convenience in use. The adequacy of the assumptions cannot be decided independently of deciding whether the theory "works," i.e., whether the predictions are accurate enough. Furthermore, the testing of assumptions may mislead a theorist away from the testing of the theory by its predictions.

That Friedman is an instrumentalist is quite evident. The apparent ambiguities and inconsistencies in his essay can best be sorted out by considering his view as instrumentalist. All methodological prescriptions that Friedman makes are subsidiary to one overriding methodological maxim—that of successful prediction.

We can further elaborate on Friedman's methodological position by considering an alternative interpretation presented by Kurt Klappholz, an economist, and Joseph Agassi, a philosopher and historian of science, in their "Methodological Prescriptions in Economics."

In their review of Friedman's essay, Klappholz and Agassi contend that Friedman's position is essentially a critical one. However, they point out that by establishing certain methodological prescriptions for progress in economics he lapses occasionally into an uncritical one.

They illustrate their criticisms by examining three propositions in Friedman's essay:

[6] For a critical discussion of instrumentalism, see Karl Popper (1969).

(a) "A hypothesis can be tested *only* by the conformity of its implications or predictions with observable phenomena" (p. 40, our italics).
(b) "Great confidence is attached to .... a [hypothesis] if it has survived many opportunities for contradiction" (p. 9)....
(c) A new or rival theory "must have implications susceptible to empirical contradiction" before it can be regarded as interesting and important (p. 38). [p. 66]

Klappholz and Agassi challenge (a) as untrue because an untestable theory may be criticized, for example, by comparing it with another theory. Furthermore, they consider it to be dogmatic to lay such a heavy emphasis on testability. If Friedman's position is interpreted as instrumentalist, it can easily be seen that testability (in Friedman's sense) is both a necessary and a sufficient condition for the acceptability of a theory.

As for (b), they point out that absence of refutation does not mean one should have greater confidence in a theory. This proposition (b) can best be understood if we note Klappholz and Agassi's view of testing. For them, testing is a test of our understanding; for Friedman, it is a search for the limits of applicability. Once the limits are established, the instrumentalist will use the theory if it is successful in predicting events of a specified kind as determined by these limits. Confidence will be attached to a theory qua instrument if it is successful in making predictions on many occasions. A theory is not considered to be "contradicted" if it is refuted. Rather it is rejected ". . . if its predictions are contradicted ("*frequently*" or *more often* than predictions from alternative hypothesis)" (Friedman, p. 9, emphasis added). In other words, what Friedman means by noncontradiction is best understood in the context of his criterion of success of a theory—it works!

Klappholz and Agassi criticize (c) because it denies a yet unfalsifiable theory from careful consideration. Friedman's overriding concern for successful predictions rules out such careful consideration for fruitful alternative theories. Referring to the criticisms of economic theory by Thorstein Veblen and others, Friedman remarks that ". . . criticism of this type is largely beside the point unless supplemented by evidence that a hypothesis differing in one or another of these respects from the theory being criticized yields better predictions for as wide a range of phenomena" (p. 31).

Again we can understand Friedman's position. A theory must be the most successful predictor before it can be given serious consideration.

As a consequence of the instrumentalist position, allegedly false statements in the theory are not problematic if the theory can give sufficiently accurate predictions. Sufficiency is determined with respect to the predictive power of all other alternative theories. Similarly, statistical relationships can be postulated between variables without explaining the mechanism linking them provided such relationships are useful in generating predictions.

IV. A Critique of Samuelson's Critique

We shall now use the interpretation of Friedman's methodology given in Section III to construct a *possible* Friedman defense against Samuelson's critique.[7] In addition we shall, independent of instrumentalism, offer a critique of Samuelson's critique.

In Section II we summarized Samuelson's criticisms as

F-Twist Theorem: It is a contradiction

[7] It is not surprising that Friedman has not replied to his critics. Presumably, he regards arguing about methodology to be like arguing about realism of a theory or its assumptions.

to maintain that all consequences can be valid and the theory and the assumptions not valid.

F-Twist Corollary: It is absurd to maintain, in the case where only some of the consequences are valid, that the theory and the assumptions are important though invalid. The parts of the theory set and the assumption set corresponding to the invalid part of the consequence set should be eliminated.

First consider the Friedman-type defense against the critique. Friedman would certainly reject the Theorem since he does not accept Samuelson's view of the desired relationship between a theory and its assumption and consequences as one of logical equivalence. In fact, Friedman considers a logical equivalency as a vice (which we may call the "S-Twist"): ". . . economic theory must be more than a structure of tautologies if it is to be able to predict and not merely to describe the consequences of action" (p. 11).

Similarly Friedman would reject the Corollary since for his instrumentalism it is irrelevant that the theory set or its assumption set is invalid since what matters is whether the theory gives sufficiently accurate predictions for the purpose at hand.

Even if elimination of the part of the theory set or the assumption set corresponding to the invalid part of the consequence set were possible it may not always be desirable to do so for instrumentalism. The corresponding part of the theory set or the assumption set may be required for the generation of the valid predictions.

What then remains of Samuelson's critique? Perhaps, his claim that Friedman is praising a theory for its shortcomings, i.e., its unrealism? It is doubtful that Friedman intends this when he says, "Truly important and significant hypotheses will be found to have 'assumptions' that are wildly inaccurate descriptive representations of reality, and, in general, the more significant the theory, the more unrealistic the assumptions (in this sense)" (p. 20). For Friedman a theory is supposed to be an abstraction. It is the convenience of the simplicity produced by an abstraction which is its primary virtue, i.e., abstraction makes it possible for a theory to be used as an instrument for prediction. As noted in Section II, Friedman regards complete descriptive realism as a vice since that would render a theory useless for prediction (see Friedman, p. 15 and Ernest Nagel (1963)).

We must therefore conclude that Samuelson's misinterpretation of Friedman's methodology has led to the failure of his critique.[3]

It remains for us to consider whether Samuelson can still maintain both the Theorem and the Corollary. Unfortunately he cannot since both propositions are beset with numerous difficulties.

Let us first consider the Theorem. Samuelson says that if C is the *complete* or *full* set of consequences of the theory, B, then C is identical or logically equivalent to B and shares the same degree of realism with B.

First, it is not clear how completeness of C is shown. A theory is considered to be complete with respect to a set of statements if that set is logically deducible from the axiom set of the theory using the given

[3] Fritz Machlup charges Samuelson to be as much an "F-Twister" as Friedman. Machlup cites Samuelson's famous factor price-equalization theorem. Samuelson acknowledges that the list of assumptions of the theorem cannot be met in the real world but that " . . . a strong polar case like this . . . can often shed useful light on factual reality" (1964, p. 737). One wonders whether the F-Twist would be acceptable to Samuelson if it were reformulated as follows: If C is empirically valid (i.e., realistic at some degree of approximation), B and A are important provided they are realistic at some degree of approximation (the degree of approximation may not be the same as that of C, but it is determined by the successfulness of C). If C is successful, then the degree of approximation of B and A is acceptable.

rule(s) of inference.[9] Consequently, the complete set must be enumerated before showing whether the set is deducible from the axiom set. Secondly, allowing for the possibility that completeness can be determined, the argument still breaks down. Because a theory is shown to be complete, it does not mean that the derived propositions or theorems, Samuelson's C, are logically equivalent to the axiom set, except in the trivial sense that the axioms imply themselves. It is rather odd, to say the least, to prove the axiom set from the theorems since the axiom set is chosen such that the theorems can be proven. Of course, the possibility remains that by complete set of consequences Samuelson means the set that is logically equivalent to the theory set.

Thirdly, even if the set of axioms is logically equivalent to the set of consequences, his position is still untenable. For a theory to be explanatory it must satisfy a number of conditions. The set of statements which forms the explanation (called the *explanans*) must logically entail the set of statements which describe what is to be explained (called the *explanandum*). The explanans must not be known to be false and be independently testable. To be independently testable the explanans must have testable consequences in addition to the explanandum. Consequently, the explanans must be richer in explanatory power and empirical content than the explanandum. Moreover, to preclude *ad hoc* explanations, the explanans must also include at least one universal law.[10]

Clearly a statement of logical equivalence has no excess empirical content. The explanans (the axiom set) is just a restatement of the explanandum (the consequence set). There is no evidence for the explanans apart from that for the explanandum.[11] Thus in the theory of consumer behavior, used by Samuelson as an example of a successful economic theory, revealed preference theory is just a restatement of the ordinal utility theory (with certain regularity assumptions). Neither theory can be considered to be an explanation of the other.

Nevertheless, supporters of Samuelson's view would deny that theories are ever explanatory and that descriptions are all that are attainable. They consider the word "explanatory" to be an honorific title conferred on a better description. We shall take up this claim in Section V. The argument about his usage of the word "minimal" can be developed on similar lines.

Having cast sufficient doubt on the view that a theory is *ideally*[12] logically equivalent to its assumptions and its consequences, we have shown that the F-Twist Theorem is at minimum highly problematic. The possibility remains that the theory, its assumptions, and its consequences can have different degrees of realism or empirical validity. Of course it is wrong to say that the consequence set can be false and the axiom set, true. By *Modus Tollens*[13] the falsity of the consequence set,

[9] The meaning of completeness, chosen here, appears to be the most appropriate since the others (see Irving Copi, ch. 6) refer to more highly axiomatized theories than those found in economics. For a different view of completeness in economics, see Boland (1970b).

[10] For further discussion of the explanatory view of theories see Popper (1957), (1968), (1969).

[11] Most philosophers are in agreement on this point. See Nagel (1961) pp. 33–37; Popper (1968), ch. 3, especially Sec. 15, (1969), pp. 385–88; Carl Hempel, pp. 30–32; and Richard Braithwaite, ch. 3, especially p. 76.

[12] Samuelson seems to see logical equivalency as a theoretical goal. This point will be discussed in greater detail in Section V.

[13] *Modus Tollens* is a rule of inference in logic by which we can validly infer from the truth of a conditional statement and of the negation of the consequent clause of the conditional statement to the truth of the negation of the antecedent clause of the conditional statement. For example, from the truth of "If Socrates is a man, then he is mortal" and the truth of "It is not the case that he is mortal," we can validly infer by *Modus Tollens* the truth of "It is not the case that Socrates is a man." For further details see any standard textbook in logic, for example, see Copi, ch. 2.

i.e., of at least one consequence, implies the falsity of the axiom set.[14] That is, if at least one of the logical consequences has been shown to be false, then we know that at least one of the antecedents is false. Whether we can find the false antecedent(s) is a difficult question to answer.[15] However, to make the above criticism of an invalid argument, we need not hold the view that a theory is logically equivalent to its consequences.

Let us now turn to the Corollary, which is closely linked to the Theorem. Samuelson argues that it is absurd to claim that a theory and its assumptions can be important though invalid if some of the consequences are invalid. He suggests that the invalid parts of the theory and of the assumptions corresponding to the invalid consequences should be eliminated.

The first part of the Corollary follows from the Theorem. On its own what it means is not clear. As to the call for the elimination of the parts of the theory and assumptions corresponding to the invalid consequences, Samuelson fails to recognize that it is not always possible to identify the corresponding parts. Furthermore, if the parts could be so identified it may not be possible to eliminate them if they are required for the explanation and prediction of the valid or true consequences. (See also fn. 14.)

We have now shown that there is not much substance to Samuelson's critique from an instrumentalist point of view. Moreover, we have shown, independently of instrumentalism, that Samuelson's critique is beset with numerous difficulties.[16]

V. Descriptivism and the Methodology of Paul Samuelson[17]

The following discussion can only be a preliminary examination of the methodology of Samuelson. Unfortunately, no account of the methodology of such an influential economist has yet appeared in economic literature. In this section attention will be given to his writings on methodological issues. A more thorough examination would require, in addition, a consideration of his methodological views that are either implicit or explicit in his writings on theoretical and policy issues.

In Section IV, it was shown that Samuelson's presentation of the relationship between a theory and its assumptions and consequences is wrong since for a theory to be explanatory and informative, it must go beyond redescription of what is to be explained.[18]

As noted in Section IV, Samuelson rejects the view that theories are explanatory. "Every description that is superseded by a 'deeper explanation' turns out upon careful examination to have been replaced by still another description, albeit possibly

[14] On falsification see Popper (1968), ch. 1, especially Sec. 6 and ch. 5.

[15] See W. V. Quine, " . . . our statements about the external world face the tribunal of sense experience not individually but only as a corporate body," (p. 41, see also pp. 42–46). See also Lakatos, Appendix.

[16] For those who do not accept the dismissal of Samuelson's critique, there is the option to criticize his meta-assumption(s) rather than his meta-conclusions, the F-Twist Theorem and the F-Twist Corollary. Now, this option should be welcomed by Samuelson as it is an important aspect of his critique of Friedman's rejection of criticism of assumptions. This option will be taken up in Section V. If we are successful in criticizing his meta-assumption(s), Samuelson must cease using the Theorem and the Corollary. Should the defenders or advocates of Samuelson's critique continue to assert them, that is, the same meta-conclusions regardless of Samuelson's meta-assumption(s), they will be caught in a contradiction. Samuelson's defenders will then be practicing Friedman's instrumentalist methodology at the meta-level.

[17] The views of Samuelson and Friedman are not mutually exclusive. In fact, Boland (1970a), (1971) maintains that they both share the same methodology, that of conventionalism. The debate is then seen as a family dispute over which conventionalist criteria has priority, generality or simplicity.

[18] By go beyond redescription, it is not suggested that a theory is therefore necessarily a false description. What is advocated is that a theory to be informative must not be a restatement of what is to be explained. Samuelson (1965a) does not seem to understand this point which was made by Gerald Massey.

a more useful description that covers, and illuminates a wider area" (1964, p. 737). An explanation is just an honorific title for a better description, that is, "*. . . a better kind of description and not something that goes ultimately beyond description*" (1965a, p. 1165; see also 1965c, p. 103).

Why does Samuelson regard a theory to be only a description and not an explanation? Why does he *want* a theory to be logically equivalent to its assumptions and to its consequences?

The answers to both questions are rooted in Samuelson's particular methodological view, a version of *descriptivism* (see Nagel (1961), especially pp. 118–29).[19] The answers given will be explanations which are not ultimate but remain always conjectural. Nevertheless, they offer reasons for Samuelson's choice of methodological position.

According to Samuelson's descriptivist methodology, 1) a theory is just a description of observable experience, a convenient and mnemonic representation of empirical reality (1952, p. 61); (1963, p. 236); (1965a, p. 1171). As a corollary, 2) knowledge consists essentially of observational reports; a theory expressible in observational language is superior to those that are not. The reasons for rejecting the view that theories are explanatory are: 3) Explanations are ultimate (1965c, pp. 102–03). 4) Apriorism must be avoided, hence theories should be expressed in observational language (1963, p. 235); (1964, p. 738). 5) Explanations turn out to be just better descriptions (1964, p. 737); (1965a, p. 1165). 6) All well-known theories in science are expressible in terms of observational statements, i.e., basic statements (1965a, p. 1167).

With the above interpretation of Samuelson's methodology, we can now see why Samuelson has logical equivalency as a theoretical goal. Since for him the object of a theory is to represent observable experiences, he considers as a successful theory one which is logically equivalent to statements of facts, the observational report. Moreover, he says that a theory is approximate, and worse off because of it, if it is not equivalent to statements of the observable reality.

Given the goal of logical equivalency, we can now consider Samuelson's view of the development of theory in science, including economics.

We can represent Samuelson's schema below. It is adapted from his 1963 paper. Each entry is a proper subset (or consequent, since the notation is used ambiguously by Samuelson) of the entry above it. In the northerly direction, there is increasing generality or universality. At each level, an attempt is made to establish a logical equivalency between a theory and its assumptions and its consequences. Once this relationship is achieved, the theoretical task is completed. A search is then made to expand the framework by another logical equivalency between a theory and its assumptions and consequences at the next level up. Samuelson has viewed as an example of successful theoretical work, the theory of consumer's behavior, because the conventional ordinal utility theory (B) was shown by Houthakker to be equivalent to the revealed preference approach (C), i.e., $B \equiv C$.

$$
\begin{array}{llll}
 & \textit{Assumptions} & \textit{Theory} & \textit{Consequences} \\
 & A+\ldots+ & \equiv B+\ldots+ & \equiv C+\ldots+ \\
\uparrow & \vdots & \vdots & \vdots \\
 & \supset & \supset & \supset \\
 & A+ & \equiv B+ & \equiv C+ \\
 & \supset & \supset & \supset \\
 & A & \equiv B & \equiv C \\
\text{Generality} & \supset & \supset & \supset \\
 & A- & \equiv B- & \equiv C- \\
 & \vdots & \vdots & \vdots
\end{array}
$$

[19] The term descriptivist is used rather than the usual descriptive because the view attacked is not that theories are descriptive but that they are *only* descriptive.

Now a refutation of Samuelson's descriptivist methodology will be given. With such a refutation, we can reject the goal of logical equivalency since it is just a specification of his descriptivist methodology.

Explanations are not ultimate. We can give explanations of explanations. Samuelson mistakenly identifies the explanatory view with an essentialist view. *Essentialism* aims at ultimate explanation which is neither capable nor in need of further explanation. It maintains that a theory goes behind the appearance of phenomena to reveal their underlying essences (see Popper (1969)). Clearly, essentialism is not a necessary part of the explanatory view.

Samuelson has rightfully condemned apriorism, the view that all phenomena can be explained as consequences of self-evident first principles, the truth of which is independent of all possible experience. But the alternative to such apriorism is not to ground theories in observational statements. For such a program is impossible to achieve because of insurmountable difficulties, both logical and epistemological.

First, the logical one, a theory is not logically equivalent to a set of observational statements because of the logical form of a theory. An observational statement, that is, a basic statement, is of the form, "There exists an x with property P at place-time r, t." A theory on the other hand includes at least one unrestricted universal statement of the form, "For all x, if x is P, then x is Q," where no spatio-temporal location is specified. A theory, therefore, cannot be logically equivalent to a set of observational statements because an unrestricted universal statement is *not* equivalent to a finite conjunction of observational statements, i.e., basic statements.

Samuelson's contention that well-known theories in science are expressible in terms of basic sentences (statements) is wrong. This contention was made in response to Massey's remarks that ". . . empirical science comes to maturity only after it effects a clean break with basic sentences, only after it boldly postulates theoretical statements that ultimately are anchored, though not submerged, in experience by means of semantic ties to basic sentences" (p. 1163).[20]

Charging Massey with using "imperialistic" vocabulary to refer to indirectly observable sentences, Samuelson claims that to accept his views would be tantamount to considering well-known theories in science to be inferior since, these too, are expressible in terms of Massey's basic sentences. Claiming the support of several physicists, Samuelson maintains that the following theories are all expressible in terms of basic sentences: Galileo's theory of falling bodies, Newtonian theory of gravitation as applied to the n-body problem, Einstein's special theory of relativity, and classical thermodynamics of Carnot, Clausius, Kelvin and pre-1900 Gibbs. However, the examples he cites cannot be so expressed. All these theories claim to be universal. For example, Galileo's theory does not apply only to a finite number of bodies but to any body. Therefore, they are not equivalent to a finite conjunction of basic sentences.

Secondly, there does not exist an independent observational language in which to ground theories and theoretical concepts. While one may accept the criticism that a theory cannot be expressed as a

[20] Much of the confusion evident in the exchange between Samuelson and Massey can be attributed to Massey's rather uncritical use of the term basic. Massey considers those sentences which are basic to be properly called true or false. Theoretical sentences can not be called true or false; their acceptance is only indirectly linked with observable experience. To draw such a distinction between theoretical and basic sentences, Massey has adopted the view that basic sentences are the fundamental and thus indisputable building blocks of scientific theories. This view overlooks the theoretical content of basic sentences and thus that theoretical sentences can be true or false.

finite conjunction of basic sentences, one still may wish to maintain that a theory is observational in so far as it contains observational terms. For example, "For all x, if x is P, then x is Q" may be considered to be observational because P and/or Q are observational terms. Unfortunately, this view cannot be maintained without encountering further difficulties. All observational terms are theory-laden. They implicitly presume theories which by their very nature go beyond just redescription of the facts. These theories prescribe lawlike behavior to certain entities. For example, such observational terms as glass or water presume lawlike behavior. We can challenge whether a container is a glass by testing the container for properties of a glass.[21]

To accept the view that all observational terms are theory-laden would be incompatible with the descriptivist position. For the view that knowledge consists essentially of observational reports is incompatible with the view that all observational terms are theory-laden. If the informative part of a statement is the observational, then we do not know what a statement is asserting unless we can separate the observational from the theoretical. But then we cannot do this.[22]

Explanations are not just better descriptions. This assertion can be supported through an examination of Samuelson's claims that Newton's theory is just a better description than Kepler's theory (1964, p. 737) and that Kepler's three laws together are necessary and sufficient conditions for the truth of Newton's theory (1965a, p. 1169). Both of these claims are false.

That Kepler's results are good approximations to Newton's is not denied. But only after Newton's theory was established were Kepler's results corrected. Further, Newton sought to explain (and consequently, corrected) Kepler's results by deducing them from more fundamental laws, the Laws of Motion and Universal Gravitation. Therefore, to say that explanations are just better descriptions is unfounded historically.

To deduce Kepler's third law from Newtonian theory, we have to assume that all planets are of the same mass. But that assumption is false. Therefore, Kepler's laws are not necessary and sufficient conditions for the truth of Newton's theory (see Max Born, pp. 129–33; Popper (1957, p. 29 and passim); Pierre Duhem, Part II, ch. 6, Section 4; and Herbert Goldstein, p. 80). Thus the refutation of Samuelson's descriptivism is completed.

With the refutation of the descriptivist view and thus, of the goal of logical equivalency we can now understand the significance of Samuelson's claim that a success was achieved when Houthakker showed the equivalence of the conventional utility approach and the revealed preference approach. Houthakker in his well-known survey of consumer theory adopts the same view as Samuelson:

> The principal qualification to Friedman's methodological position that needs to be made is that in a well-developed theory the distinction between assumptions and conclusions disappears. If a theory reaches logical (as opposed to empirical) perfection, the assumptions under which any conclusion is derived are just strong enough for that purpose; in other words the assumptions are necessary and sufficient for the conclusions, and each may be judged by the other. The theory then becomes a list of equivalent relations between two sets of concepts, neither one of which is more fundamental than the other.
>
> [1961, p. 705]

[21] See Popper (1968, especially Appendix *x) for a more detailed discussion of this point. For a somewhat different view of theory-ladenness see Kuhn and for a critical assessment of Kuhn's view see articles in Lakatos and Musgrave.

[22] For a devastating criticism of sensationalism of which descriptivism is a part, see Agassi.

As noted earlier, if we show that a theory is logically equivalent to its assumptions and to its consequences, then we must reject the theory as an *explanation* of the consequences and the assumptions as an *explanation* of the theory. A set of statements used to explain another set of statements cannot itself be explained by the other set of statements. One may ask what purpose is served by choosing to group statements under the categories: assumptions, theory, and consequences. For Samuelson's descriptivism, the choice has no epistemological basis, only a conventional (arbitrary) one.

Samuelson cites as an example of a well-developed theory, the theory of consumer behavior: "The doctrines of revealed preference provide the most literal example of a theory that has been stripped down to its bare implications for empirical realism: Occam's Razor has cut away every zipper, collar, shift, and fig leaf" (1964, p. 738).

Referring to the work of Houthakker on revealed preference, Samuelson asserts ". . . that the conventional theory has *no* wider implications than these prosaic factual implications [i.e., one never observes the contradiction of the Strong Axiom]. Once the two formulations had been rigorously proved to imply each other mutually, that issue was settled" (1964, p. 738).

These comments on the development of the theory of consumer's behavior are rather curious. The theory of revealed preference was originally offered as a replacement for the ordinal utility theory because Samuelson wished to rid the theory of consumer behavior of all dependence on empirically untestable hedonistic psychology and utilitarian philosophy (1938), (1965b). The Strong and Weak Axioms were considered to be the empirically testable versions of the theory of consumer behavior. With the work of Houthakker (1950) and Hirofumi Uzawa we now know that the two versions of the theory are logically equivalent. Hence, the revealed preference version is no more testable than the ordinal utility version. In fact, no desired goals appear to be achieved by this new approach. If so, why does Samuelson still advocate the pursuit of logical equivalencies?

That Samuelson seeks logical equivalencies is evident by considering his view of the role of deduction: ". . . it is clear that deduction has the modest linguistic role of translating certain empirical hypotheses into their 'logical equivalents' " (1952, p. 57; see also 1965b, p. 12). In terms of the analysis in Section IV, the logical equivalent of an empirical hypothesis (theory) is presumably the complete consequence set. Samuelson's view of the *role* of deduction seems rather unusual. This view of the role of deduction is only compatible with the goal of logical equivalency.

Nevertheless, Samuelson insists that we *always* derive logical equivalents in deduction:

> Actually, if proposition A correctly implies proposition B, and B correctly implies proposition C, and so forth all the way to Z, then it is necessarily true that A implies Z in every sense that it implies B. There can be no leakage of truth at any stage of a valid deductive syllogism. All such syllogisms are mere translations of the type, "A rose is a rose is a rose." [1952, p. 58]

A implies Z does not mean that Z is logically equivalent to A. For A to be logically equivalent to Z, we must show that A implies Z and Z implies A.

While we can, if we so wish, regard the *role* of deduction as one of deducing logical equivalents from empirical hypotheses, it is wrong to assert that *all* logical consequents are logical equivalents.

VI. What Is Not the Methodological Choice?

While the paper has been primarily directed to the refutation of Samuelson's

espoused methodology, it should now be clear that the refutation should not be interpreted as a vindication of Friedman's position.

Throughout the debate in economic literature the choice has been between either Friedman's or Samuelson's position. Unrealism is regarded as a Samuelson vice (the F-Twist) but in some sense a Friedman virtue (in view of instrumentalism); pure description, the end of which is a logical equivalency, a Friedman vice (which in Section IV we have called the S-Twist) but a Samuelson virtue (in view of descriptivism). Descriptivism was shown to be untenable in view of logical and epistemological difficulties but instrumentalism cannot be defeated in a similar fashion.

In fact no refutation appears possible. Although Samuelson's descriptivism does not allow a valid critique of Friedman's instrumentalism, one can appreciate the spirit of Samuelson's F-Twist caricature, namely, that Friedman's methodology is fundamentally anti-intellectual. Instrumentalism provides a self-justification for its methods and its methodological choices. This self-justification is quite apparent in view of the current controversy about the *new monetarism* over such issues as the relation of the money supply to the money *GNP*. Harry Johnson attributes in part the rise of the new monetarism to Friedman's methodology: ". . . the methodology of positive economics was an ideal methodology for justifying work that produced apparently surprising results without feeling obliged to explain just why they occurred and in so doing mystifying and exciting the interest of noncommitted economists and wavering Keynesians" (p. 13).

However, he correctly notes the limitation of instrumentalism and the difficulty involved in defeating it: "The demand for clarification of the mechanism by which results can be explained is contrary to the methodology of positive economics with its reliance on the 'as if' approach" (p. 13).

Why does it matter if we choose one methodology or another? Why should we even be *self-conscious* of our methodological choices?

Although perhaps not immediately obvious, many economic controversies are at their roots, methodological ones.[23] In addition to the dispute over the new monetarism, explicit methodological considerations may throw light on a controversy which has enthralled the leading economic theoreticians for over twenty years, the controversy over the theory of capital and growth.[24]

We can briefly consider two recent results in the raging controversy. In challenging Robert Solow's claim of the importance of Irving Fisher's concept of the "rate of return" to the determination of the "rate of profit," Luigi Pasinetti points out:

> After *calling* "social rate of return" the rate of profit at which two economic systems are equally profitable one should not be surprised to find that the social rate of return so defined is indeed, in all circumstances, equal to the rate of profit at which the two economic systems are equally profitable. This has become a tautological assertion, which no doubt is always true but which cannot prove anything on any theory of the rate of profit. [1969, p. 526]

And furthermore, he points out that one may *choose* to use the words the "rate of return" as a synonym for the "rate of profit" but that one cannot ". . . obviously pretend to use the notion of rate of return to *explain* the rate of profit" (p. 529, see also (1970)).

Solow retorts that it is silly to call it tautological: "*Any* deductive proposition

[23] With Houthakker's result, one would have expected a controversy to develop in the theory of consumer behavior.

[24] For a detailed exposition of the main issues, see G. C. Harcourt.

is tautological; one can only say that some are less obvious or less interesting than others" (p. 425, emphasis added). It would appear that Solow shares the same view as Samuelson on the role of deduction and the role of theories.

Finally, consider the recent results on the usefulness of the Cobb-Douglas production function to *explain* the relative constancy of shares going to labor and capital. Commenting on the measure of capital controversy, Joan Robinson reports on the apparent success of the Cobb-Douglas function:

> The suggestion is clear, however, that labor's share is not roughly constant because the diverse technical relationships of modern economies are truly representable by an aggregate Cobb-Douglas but rather that such relationships appear to be representable by an aggregate Cobb-Douglas *because* labor's share happens to be roughly constant. [F. Fisher, *Rev. Econ. Statist.*, Nov. 1971, as quoted in Robinson (1971, p. 602).]

Of course, the way is open for the rebuttal that the Cobb-Douglas is not really to *explain* but to *describe* the empirical relationships found in economies.

The above examples are suggestive of the possibilities open to explicit methodological considerations in sorting out the issues at stake in economic controversies.

What then is the methodological choice? It surely is not instrumentalism or descriptivism. Instrumentalism in its single-minded pursuit of predictions *goes* "beyond the facts" by considering the truth or falsity of statements to be irrelevant; descriptivism in its pursuit of pure descriptions designs a theory *not to go* beyond the facts and thus ends up with a theory being just a restatement of the "facts."

As an alternative to the two views, we have advocated the view that a theory is explanatory and informative, namely, that in order to have any explanatory content it must go beyond pure description.

Hence, the descriptivist goal of logical equivalency denies a theory any explanatory content while the instrumentalist's particular obsession with predictions disregards the explanatory content of a theory.

The choice, then, is *not* between instrumentalism and descriptivism but between them *both* and the view that a theory is explanatory and informative, one which provides an answer, albeit a tentative one, to the question, "Why?"

Some International Evidence on Output-Inflation Tradeoffs

By Robert E. Lucas, Jr.*

This paper reports the results of an empirical study of real output-inflation tradeoffs, based on annual time-series from eighteen countries over the years 1951–67. These data are examined from the point of view of the hypothesis that average real output levels are invariant under changes in the time pattern of the rate of inflation, or that there exists a "natural rate" of real output. That is, we are concerned with the questions (i) does the natural rate theory lead to expressions of the output-inflation relationship which perform satisfactorily in an econometric sense for all, or most, of the countries in the sample, (ii) what testable restrictions does the theory impose on this relationship, and (iii) are these restrictions consistent with recent experience?

Since the term "natural rate theory" refers to varied aggregation of models and verbal developments,[1] it may be helpful to sketch the key elements of the particular version used in this paper. The first essential presumption is that *nominal* output is determined on the aggregate demand side of the economy, with the division into real output and the price level largely dependent on the behavior of *suppliers* of labor and goods. The second is that the partial "rigidities" which dominate short-run supply behavior result from suppliers' lack of information on some of the prices relevant to their decisions. The third presumption is that inferences on these relevant, unobserved prices are made optimally (or "rationally") in light of the stochastic character of the economy.

As I have argued elsewhere (1972), theories developed along these lines will *not* place testable restrictions on the coefficients of estimated Phillips curves or other single equation expressions of the tradeoff. They will not, for example, imply that money wage changes are linked to price level changes with a unit coefficient, or that "long-run" (in the usual distributed lag sense) Phillips curves must be vertical. They *will* (as we shall see below) link supply parameters to parameters governing the stochastic nature of demand shifts. The fact that the implications of the natural rate theory come in this form suggests an attempt to test it using a sample, such as the one employed in this study, in which a wide variety of aggregate demand behavior is exhibited.

In the following section, a simple aggregative model will be constructed using the elements sketched above. Results based on this model are reported in Section II, followed by a discussion and conclusions.

I. An Economic Model

The general structure of the model developed in this section may be described very simply. First, the aggregate price-quantity observations are viewed as intersection points of an aggregate demand and an aggregate supply schedule. The former is drawn up under the assumption of a cleared money market and represents the output-price level relationship implicit in

* Graduate School of Industrial Administration, Carnegie-Mellon University.

[1] The most useful, general statements are those of Milton Friedman (1968) and Edmund Phelps. Specific illustrative examples are provided by Donald Gordon and Allan Hynes and Lucas (April 1972).

the standard IS-LM diagram. It is viewed as being shifted by the usual set of demand-shift variables: monetary and fiscal policies and variation in export demands. The supply schedule is drawn under the assumption of a cleared labor market; its slope therefore reflects labor and product market "rigidities."

The structure of this model, which is essentially that suggested in Lucas and Leonard Rapping (1969), will be greatly simplified by an additional special assumption: that the aggregate demand curve is unit elastic.[2] In this case, the level of nominal output can be treated as an "exogenous" variable with respect to the goods market, and the entire burden of accounting for the breakdown of nominal income into real output and price is placed on the aggregate supply side. In the next subsection, *A*, a supply model designed to serve this purpose is developed. In subsection *B*, solutions to the full (demand and supply) model are obtained.

A. Aggregate Supply

All formulations of the natural rate theory postulate rational agents, whose decisions depend on *relative* prices only, placed in an economic setting in which they cannot distinguish relative from general price movements. Obviously, there is no limit to the number of models one can construct where agents are placed in this situation of imperfect information; the trick is to find tractable schemes with this feature. One such model is developed below.

We imagine suppliers as located in a large number of scattered, competitive markets. Demand for goods in each period is distributed unevenly over markets, leading to relative as well as general price movements. As a consequence, the situation as perceived by individual suppliers will be quite different from the aggregate situation as seen by an outside observer. Accordingly, we shall attempt to keep these two points of view separate, turning first to the situation faced by individual suppliers.

Quantity supplied in each market will be viewed as the product of a normal (or secular) component common to all markets and a cyclical component which varies from market to market. Letting z index markets, and using y_{nt} and y_{ct} to denote the *logs* of these components, supply in market z is:

$$y_t(z) = y_{nt} + y_{ct}(z) \tag{1}$$

The secular component, reflecting capital accumulation and population change, follows the trend line:

$$y_{nt} = \alpha + \beta t \tag{2}$$

The cyclical component varies with perceived, *relative* prices and with its own lagged value:

$$y_{ct}(z) = \gamma[P_t(z) - E(P_t \mid I_t(z))] + \lambda y_{c,t-1}(z) \tag{3}$$

where $P_t(z)$ is the actual price in z at t and $E(P_t \mid I_t(z))$ is the mean current, general price level, conditioned on information available in z at t, $I_t(z)$.[3] Since y_{ct} is a deviation from trend, $|\lambda| < 1$.

[2] An explicit derivation of the price-output relationship from the IS-LM framework is given by Frederic Raines. Of course, this framework does not imply an elasticity of unity, though it is consistent with it. Since the unit elasticity hypothesis is primarily a matter of convenience in the present study, I shall comment below on the probable consequences of relaxing it.

[3] A supply function for labor which varies with the ratio of actual to expected prices is developed and verified empirically by Lucas and Rapping (1969). The effect of lagged on actual employment is also shown. In our 1972 paper, in response to Albert Rees's criticism, we found that this persistence in employment cannot be fully explained by price expectations behavior. Both these effects—an expectations and a persistence effect—will be transmitted by firms to the goods market. In addition, they are probably augmented by speculative behavior on the part of firms (as analyzed for example, by Paul Taubman and Maurice Wilkinson).

For a general equilibrium model in which suppliers behave essentially as given by (3), see my 1972 papers.

The information available to suppliers in z at t comes from two sources. First, traders enter period t with knowledge of the past course of demand shifts, of normal supply y_{nt}, and of past deviations $y_{c,t-1}$, $y_{c,t-2}$, ... While this information does not permit exact inference of the *log* of the current general price level, P_t, it does determine a "prior" distribution on P_t, common to traders in all markets. We assume that this distribution is known to be normal, with mean $\bar{P}_t$ (depending in a known way on the above history) and a constant variance σ^2.

Second, we suppose that the actual price deviates from the (geometric) economy-wide average by an amount which is distributed independently of P_t. Specifically, let the percentage deviation of the price in z from the average P_t be denoted by z (so that markets are indexed by their price deviations from average) where z is normally distributed, independent of P_t, with mean zero and variance τ^2. Then the observed price in z, $P_t(z)$ (in *logs*) is the sum of independent, normal variates

$$P_t(z) = P_t + z \tag{4}$$

The information $I_t(z)$ relevant for estimation of the unobserved (by suppliers in z at t) P_t, consists then of the observed price $P_t(z)$ and the history summarized in $\bar{P}_t$.

To utilize this information, suppliers use (4) to calculate the distribution of P_t, conditional on $P_t(z)$ and $\bar{P}_t$. This distribution is (by straightforward calculation) normal with mean:

$$\begin{aligned} E(P_t \mid I_t(z)) &= E(P_t \mid P_t(z), \bar{P}_t) \\ &= (1-\theta)P_t(z) + \theta\bar{P}_t \end{aligned} \tag{5}$$

where $\theta=\tau^2/(\sigma^2+\tau^2)$, and variance $\theta\sigma^2$. Combining (1), (3), and (5) yields the supply function for market z:

$$\begin{aligned} y_t(z) = y_{nt} &+ \theta\gamma[P_t(z) - \bar{P}_t] \\ &+ \lambda y_{c,t-1}(z) \end{aligned} \tag{6}$$

Averaging over markets (integrating with respect to the distribution of z) gives the aggregate supply function:

$$\begin{aligned} y_t = y_{nt} &+ \theta\gamma(P_t - \bar{P}_t) \\ &+ \lambda[y_{t-1} - y_{n,t-1}] \end{aligned} \tag{7}$$

The *slope* of the aggregate supply function (7) thus varies with the fraction θ of *total* individual price variance, $\sigma^2+\tau^2$, which is due to *relative* price variation. In cases where τ^2 is relatively small, so that individual price changes are virtually certain to reflect general price changes, the supply curve is nearly vertical. At the other extreme when general prices are stable (σ^2 is relatively small) the slope of the supply curve approaches the limiting value of γ.[4]

B. Completion and Solution of the Model

A central assumption in the development above is that supply behavior is based on the *correct* distribution of the unobserved current price level, P_t. To proceed, then, it is necessary to determine what this correct distribution is, a step which requires the completion of the model by inclusion of an aggregate demand side.

As suggested earlier, this will be done by postulating a demand function for goods of the form:

$$y_t + P_t = x_t \tag{8}$$

where x_t is an exogenous shift variable—equal to the observable *log* of nominal *GNP*. Further, let $\{\Delta x_t\}$ be a sequence of independent, normal variates with mean δ and variance σ_x^2.[5]

[4] This predicted relationship between a supply elasticity and the variance of a component of the price series is analogous to the link between the income elasticity of consumption demand and the variances of permanent and transitory income components which Friedman (1957) observes. As will be seen in Section II, it works in empirical testing in much the same way as well.

[5] This particular characterization of the "shocks" to the economy is not central to the theory, but to discuss

The relevant history of the economy then consists (at most) of y_{nt} (which fixes calendar time), the demand shifts x_t, $x_{t-1}, \ldots$, and past actual real outputs $y_{t-1}, y_{t-2}, \ldots$. Since the model is linear in *logs*, it is reasonable to conjecture a price solution of the form:[6]

$$P_t = \pi_0 + \pi_1 x_t + \pi_2 x_{t-1} + \pi_3 x_{t-2} + \ldots + \eta_1 y_{t-1} + \eta_2 y_{t-2} + \ldots + \xi_0 y_{nt} \tag{9}$$

Then $\overline{P}_t$ will be the expectation of P_t, based on all information *except* x_t (the current demand level) or:

$$\begin{aligned}\overline{P}_t = \overline{P}_0 &+ \pi_1(x_{t-1} + \delta) + \pi_2 x_{t-1} \\ &+ \pi_3 x_{t-2} + \ldots + \eta_1 y_{t-1} \\ &+ \eta_2 y_{t-2} + \ldots + \xi_0 y_{nt}\end{aligned} \tag{10}$$

To solve for the unknown parameters π_i, η_j and ξ_0 we first eliminate y_t between (7) and (8), or equate quantity demanded and supplied. Then inserting the right sides of (9) and (10) in place of P_t and $\overline{P}_t$, one obtains an identity in $\{x_t\}$, $\{y_t\}$, and y_{nt}, which is then used to obtain the parameter values. The resulting solutions for price and output are:[7]

$$P_t = \frac{\theta\gamma\delta}{1+\theta\gamma} - \lambda\beta + \frac{1}{1+\theta\gamma} x_t + \frac{\theta\gamma}{1+\theta\gamma} x_{t-1} - \lambda y_{t-1} - (1-\lambda) y_{nt}$$

$$y_t = -\frac{\theta\gamma\delta}{1+\theta\gamma} + \lambda\beta + \frac{\theta\gamma}{1+\theta\gamma}\Delta x_t + \lambda y_{t-1} + (1-\lambda) y_{nt}$$

In terms of ΔP_t and y_{ct}, and letting $\pi = \theta\gamma/(1+\theta\gamma)$, the solutions are:

$$y_{ct} = -\pi\delta + \pi\Delta x_t + \lambda y_{c,t-1} \tag{11}$$

$$\Delta P_t = -\beta + (1-\pi)\Delta x_t + \pi\Delta x_{t-1} - \lambda\Delta y_{c,t-1} \tag{12}$$

Let us review these solutions for internal consistency. Evidently, P_t is normally distributed about $\overline{P}_t$. The conditional variance of P_t will have the constant (as assumed) variance $1/(1+\theta\gamma)^2\sigma_x^2$. Thus those features of the behavior of prices which were assumed "known" by suppliers in subsection A are, in fact, true in this economy.

To review, equations (11) and (12) are the *equilibrium values* of the inflation rate and real output (as a percentage deviation from trend). They give the intersection points of an aggregate demand schedule, shifted by changes in x_t, and an aggregate supply schedule shifted by variables (lagged prices) which determine expectations. In order to avoid the introduction of an additional, spurious "expectations parameter," one cannot solve for this intersection on a period-by-period basis; accordingly, we have adopted a method which yields equilibrium "paths" of prices and output. Otherwise, the interpretation of (11) and (12) is entirely conventional.

Not surprisingly, the solution values of inflation and the cyclical component of real output are indicated by (11) and (12) to be distributed lags of current and past changes in nominal output. A change in the nominal expansion rate, Δx_t, has an immediate effect on real output, and lagged effects which decay geometrically. The

rational expectations formation at all, *some* explicit stochastic description is clearly required. Independence is used here partly for simplicity, partly because it is empirically roughly accurate for most countries in the sample. The effect of autocorrelation in the shocks would, as can be easily traced out, be to add higher order lag terms to the solutions found below.

[6] This solution method is adapted from Lucas (1972), which is in turn based on the ideas of John Muth.

[7] If a demand function of the form $y_t = \xi P_t + x_t$ had been used, these solutions would assume the same form, with different expressions for the coefficients. If $\xi \neq 1$, however, x_t is an unobserved shock, unequal in general to observed nominal income. In this case, the model still predicts the time-series structure (moments and lagged moments) of the series y_{ct} and ΔP_t and is thus, in principle, testable. I have found empirical experimenting along these lines suggestive, but the series used are simply too short to yield results of any reliability.

immediate effect on prices is one minus the real output effect, with the remainder of the impact coming in the succeeding period. We note in particular that this lag pattern may well produce periods of simultaneous inflation and below average real output. Though these periods arise because of supply shifts, the shifts result from lagged perception of demand changes, and *not* from autonomous changes in the cost structure of suppliers.

In addition to these features, the model does indeed assert the existence of a natural rate of output: the *average* rate of demand expansion, δ, appears in (11) with a coefficient equal in magnitude to the coefficient of the current rate, and with the opposite sign. Thus changes in the average rate of nominal income growth will have *no* effect on average real output. On the other hand, unanticipated demand shifts do have output effects, with magnitude given by the parameter π. Since this effect depends on "fooling" suppliers (in the sense of subsection A), one expects that π will be larger the smaller the variance of the demand shifts. We next develop this implication explicitly.

From the definition of π in terms of θ and γ, and the definition of θ in terms of σ^2 and τ^2 we have

$$\pi = \frac{\tau^2\gamma}{\sigma^2 + \tau^2(1+\gamma)}$$

Combining with the expression for σ^2 obtained above, this gives

$$\pi = \frac{\tau^2\gamma}{(1-\pi)^2\sigma_x^2 + \tau^2(1+\gamma)} \tag{13}$$

For fixed τ^2 and γ, then, π takes the value $\gamma/(1+\gamma)$ at $\sigma_x^2=0$ and tends monotonically to zero as σ_x^2 tends to infinity.

The prediction that the average deviation of output from trend, $E(y_{ct})$, is invariant under demand policies is not, of course, subject to test: the deviations from a *fitted* trend line must average to zero. Accordingly, we must base tests of the natural rate hypothesis (in this context) on (13): a relationship between an observable variance and a slope parameter.

II. Test Results

Testing the hypothesis advanced above involves two steps. First, within each country (11) and (12) should perform reasonably well. In particular, under the presumption that demand fluctuations are the major source of variation in ΔP_t and y_{ct}, the fits should be "good." The estimated values of π and λ should be between zero and one. Finally, since (11) and (12) involve five slope parameters but only two theoretical ones, the estimated π and λ values obtained from fitting (11) should work reasonably well in explaining variations in ΔP_t.

The main object of this study, however, is not to "explain" output and price level movements within a given country, but rather to see whether the terms of the output-inflation "tradeoff" vary across countries in the way predicted by the natural rate theory. For this purpose, we shall utilize the theoretical relationship (13) and the estimated values of π and σ_x^2. Under the assumption that τ^2 and γ are relatively stable across countries, the estimated π values should decline as the sample variance of Δx_t increases.

Descriptive statistics for the eighteen countries in the sample are given in Table 1.[8] As is evident, there is no association

[8] The raw data on real and nominal *GNP* are from *Yearbook of National Accounts Statistics*, where series from many countries are collected and put on a uniform basis. The choice of countries is by no means random: the eighteen used are all the countries from which continuous series are available. The sample could thus be broadened considerably by use of sources from individual countries. To obtain the variables used in the tests, the *logs* of real and nominal output, y_t and x_t, are *logs* of the series in the source. The *log* of the price level, P_t, is the difference $x_t - y_t$; y_{ct} is the residual from the trend line $y_t = a + bt$, fit by least squares from the sample

TABLE 1—DESCRIPTIVE STATISTICS, 1952–67

Country	Mean Δy_t	Mean ΔP_t	Variance y_{ct}	Variance ΔP_t	Variance Δx_t
Argentina	.026	.220	.00096	.01998	.01555

Norway	.038	.034	.00092	.00033	.00098
Paraguay	.054	.157	.00488	.03192	.03450
Puerto Rico	.058	.024	.00205	.00021	.00077
Sweden	.039	.036	.00030	.00043	.00041
United Kingdom	.028	.034	.00022	.00037	.00014
United States	.036	.019	.00105	.00007	.00064
Venezuela	.060	.016	.00175	.00068	.00127

between average real growth rates and average rates of inflation: this fact seems to be consistent with both the conventional and natural rate views of the tradeoff. Since our interest is in comparing real output and price behavior under different time patterns of nominal income, these statistics are somewhat disappointing. Essentially two types of nominal income behavior are observed: the highly volatile and expansive policies of Argentina and Paraguay, and the relatively smooth and moderately expansive policies of the remaining sixteen countries. But if the sample provides only two "points," they are indeed widely separated: the estimated variance of demand in the high inflation countries is on the order of 10 times that in the stable price countries.

The first three columns of Table 2 summarize the performance of equation (11) in accounting for movements in y_{ct}. The estimated values for π all lie between zero and one; with the exceptions of Argentina and Puerto Rico, so do the estimated λ values. The R^2s indicate that for many, or perhaps most countries, important output-determining variables have been omitted from the model. The R^2s for the inflation rate equation, (12), are given in column (4) of Table 2. In general, these tend to be lower than for equation (11), and not surprisingly the estimated coefficients from (12) (which are not shown) tend to behave erratically. Column (5) of Table 2 gives the fraction of the variance of ΔP_t explained by (12) when the coefficient estimates from (11) are imposed. (A "−" indicates a negative value.)[9]

With respect to its performance as an intracountry model of income and price determination, then, the system (11)–(12) passes the formal tests of significance. On the other hand, the goodness-of-fit statis-

period. The moments given in Table 1 are maximum likelihood estimates based on these series. The estimates reported in Table 2 are by ordinary least squares.

[9] The loss of explanatory power when these coefficients are imposed on (12) can be assessed formally by an approximate Chi-square test. By this measure, the loss is significant at the .05 level for Paraguay only. As Table 2 shows, however, this test is somewhat deceptive: for several countries the least squares estimates of (12) are so poor that there is little explanatory power to lose, and the test is "passed" vacuously.

TABLE 2—SUMMARY STATISTICS BY COUNTRY, 1953–67

Country	π	λ	R_y^2	$R_{\Delta P}^2$	R_ω^2

Venezuela	.514 (.183)	.937 (.148)	.755	.425	—

tics are generally considerably poorer than we have come to expect from annual time-series models.

In contrast to these somewhat mixed results, the behavior of the estimated π values across countries is in striking conformity with the natural rate hypothesis. For the sixteen stable price countries, $\hat{\pi}$ ranges from .287 to .910; for the two volatile price countries, this estimate is smaller by a factor of 10! To illustrate this order-of-magnitude effect more sharply, let us examine the complete results for two countries: the United States and Argentina. For the United States, the fitted versions of (11) and (12) are:

$$y_{ct} = -.049 + (.910)\Delta x_t + (.887)y_{c,t-1}$$

$$\Delta P_t = -.028 + (.119)\Delta x_t + (.758)\Delta x_{t-1} - (.637)\Delta y_{c,t-1}$$

The comparable results for Argentina are:

$$y_{ct} = -.006 + (.011)\Delta x_t - (.126)y_{c,t-1}$$

$$\Delta P_t = -.047 + (1.140)\Delta x_t - (.083)\Delta x_{t-1} + (.102)\Delta y_{c,t-1}$$

In a stable price country like the United States, then, policies which increase nomi-

nal income tend to have a large initial effect on real output, together with a small, positive initial effect on the rate of inflation. Thus the apparent short-term tradeoff is favorable, as long as it remains unused. In contrast, in a volatile price country like Argentina, nominal income changes are associated with equal, contemporaneous price movements with no discernible effect on real output. These results are, of course, inconsistent with the existence of even moderately stable Phillips curves. On the other hand, they follow directly from the view that inflation stimulates real output if, and only if, it succeeds in "fooling" suppliers of labor and goods into thinking *relative* prices are moving in their favor.

III. Concluding Remarks

The basic idea underlying the tests reported above is extremely simple, yet I am afraid it may have become obscured by the rather special model in which it is embodied. In this section, I shall try to restate this idea in a way which, though not quite accurate enough to form the basis for econometric work, conveys its essential feature more directly.

The propositions to be compared empirically refer to the effects of aggregate demand policies which tend to move inflation rates and output (relative to trend) in the same direction, or alternatively, unemployment and inflation in opposite directions. The conventional Phillips curve account of this observed co-movement says that the terms of the tradeoff arise from relatively stable structural features of the economy, and are thus independent of the nature of the aggregate demand policy pursued. The alternative explanation of the same observed tradeoff is that the positive association of price changes and output arises because suppliers misinterpret general price movements for relative price changes. It follows from this view, first, that changes in average inflation rates will not increase average output, and secondly, that the higher the *variance* in average prices, the less "favorable" will be the observed tradeoff.

The most natural cross-national comparison of these propositions would seem to be a direct examination of the association of average inflation rates and average output, relative to "normal" or "full employment." Unfortunately, there seems to be no satisfactory way to measure normal output. The deviation-from-fitted-trend method I have used *defines* normal output to be average output. The use of unemployment series suffers from the same difficulty, since one must somehow select the (obviously positive) rate to be denoted full employment.

Thus although the issue revolves around the relation between *means* of inflation and output rates, it cannot be resolved by examination of sample averages. Fortunately, the existence of a stable tradeoff also implies a relationship between *variances* of inflation and output rates, as illustrated in Figure 1. With a stable tradeoff, policies which lead to wide variation in prices must also induce comparable variation in real output. If these sample variances do not tend to move together (and, as Table 1 shows, they do not) one

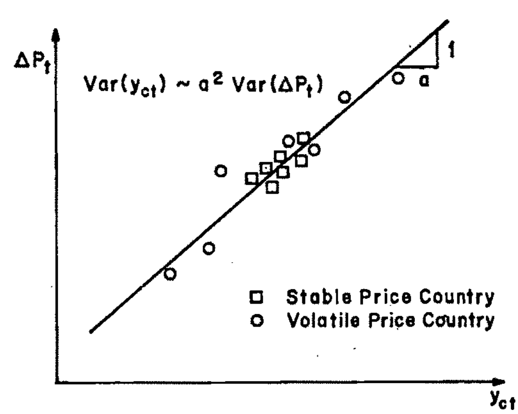

FIGURE 1

can only conclude that the tradeoff tends to fade away the more frequently it is used, or abused.

This simple argument leads to a formal test if the output-inflation association is entirely contemporaneous. In fact, however, it involves lagged effects which make a direct comparison of variances, as just suggested, difficult in short time-series. Accordingly, it has been necessary to impose a specific, simple structure on the data. As we have seen, this structure accounts for output and inflation rate movements only moderately well, but well enough to capture the main phenomenon predicted by the natural rate theory: the higher the variance of demand, the more unfavorable are the terms of the Phillips tradeoff.

A Note on the Concept and Measure of Consumer's Surplus

By Michael E. Burns*

In an important new book, E. J. Mishan is critical of statements made by prominent economists that have thrown doubt on the usefulness of the concept of consumer's surplus. Mishan goes on to draw attention to the need for clarification of ". . . the concept itself, and the relationship between the concept and its measurable proxy, the demand curve" (1971, pp. 325–28). A fundamental obstacle to such clarification would appear to be a view quite generally held by economists, and formally stated by Paul Samuelson that ". . . the Marshallian concept of consumer's surplus does not refer to any one thing, but to at least half a dozen interrelated expressions."[1] Accordingly the approach offered here begins with a reinterpretation of the literature normally associated with the origins of the concept in question.

There is general acknowledgement that J. Dupuit gave the first description (1844) of the notion that Alfred Marshall later referred to in 1920 as consumer's surplus. What is generally forgotten is that Dupuit's primary concern was the *monetary* evaluation of the benefits (or losses) associated with alternative price policies for a public good.[2] His famous but perhaps slightly ambiguous conclusion may be illustrated using the toll-bridge example; the consumer's gain in *utility* brought about by the reduction in a toll should be measured in *money* terms by the area to the left of the demand curve (for the use of the bridge), between the old and new toll (price) levels.[3] His justification for the accuracy of this measure followed from two considerations. Firstly, his attempts at rationalization were influenced by considerations of services of an indivisible nature and led him to the plausible view that the monetary evaluation of the additional utility obtained from the purchase of a good should be taken as ". . . that maximum sacrifice (in income) that each consumer would be prepared to make, in order to be able to make the purchase of the good."[4] Secondly, Dupuit believed that the magnitude of this sacrifice was exactly measured in terms of the areas to the left of the demand curve. Any faults in the justification of the suggested evaluation of the benefits concerned should not conceal the unique nature of the concept whose measure was being sought.

Marshall's contribution followed very similar lines, but with the important qualification that the accuracy of the measure 'what a consumer would pay, rather than go without' required that the marginal utility of income be constant.[5]

* I have benefitted from discussions with colleagues at The University of Western Australia, and from the valuable comments of the referees on an earlier draft of this paper. Needless to say, all remaining errors are my own responsibility.

[1] See Samuelson (1947), pp. 197–202. Samuelson's discussions here are based on an earlier paper (1942), where he considered in detail the question of the constancy of the marginal utility of income.

[2] See Dupuit, in *Readings in Welfare Economics*, pp. 253–83.

[3] See Dupuit, in *Readings in Welfare Economics*, particularly pp. 270–71.

[4] In the original version, Dupuit wrote "L'économie politique doit prendre pour mesure de l'utilité d'un objet le sacrifice maximum que chaque consommateur serait disposé à faire pour se le procurer" (p. 40).

[5] See Marshall, p. 842. There is often some confusion between the marginal utility of income and that of money. In the text we are always referring to the former concept. Don Patinkin, (1956), p. 65, makes the distinc-

However it is interesting to reconsider Marshall's introduction of the now familiar terminology, substituting the expression *gain in utility* for what Marshall referred to as a surplus of satisfaction:

> . . . [the consumer] derives from a purchase a surplus of satisfaction [gain in utility]. The excess of the price which he would be willing to pay rather than go without the thing, over that which he actually does pay, is the economic [money] measure of this surplus of satisfaction [gain in utility]. It may be called consumer's surplus. [p. 124]

It is perhaps signficant that J. R. Hicks, without explicitly making the substitution of terms suggested above, concluded that ". . . the best way of looking at consumer's surplus is to regard it as a means of expressing, in terms of money income, the gain which accrues to the consumer as a result of a price fall" (1947, p. 40).

The substantial agreement amongst these authors as to the precise nature of the concept they sought to measure provides a basis for the treatment given in this paper. Accordingly, in Section I it is shown that for an individual the "income equivalent" of a utility change effected by a *ceteris paribus* price change is in exact agreement with Dupuit's original measure. In Section II, I reconsider two of the alternative expressions that have been offered as measures of the income equivalent of such a utility change. Fresh insight is given into the approximations that are implicit in these expressions. Finally, in Section III, the basic results are extended in a number of directions. Questions concerning the market demand curve, the meaning of areas to the left of the demand curve and the possibility of evaluating utility changes effected by changes in more than one variable are all examined in some detail.

tion between the two terms quite clear, as does Samuelson (1947), p. 190.

I. The Income Equivalent of a Utility Change

Before we undertake the formal derivation, some insight can be obtained by considering a simple illustrative example. Suppose quite generally that some of the conditions facing a utility maximizing consumer are altered, so that the consumer moves to a new equilibrium position, undergoing a change in the level of his total utility. Suppose further that the changes in each of the variables concerned are sufficiently small for the marginal utility of income to be treated as constant throughout the movement. Given any such change in utility, and the relevant value of the marginal utility of income, there must exist a sum of money (an income equivalent) that satisfies the relationship

$$\begin{aligned}&\text{(Change in Utility)}\\ &\equiv \text{(marginal utility of income)}\\ &\times \text{(income equivalent)}\end{aligned} \tag{1}$$

Given that the marginal utility of income cannot be constant everywhere, we may thus note that equal utility changes between different pairs of situations would generally be expected to yield different income equivalents.

Let us now consider the position of a utility-maximizing consumer, whose (ordinal) utility function is described by

$$U = f(x_1 \ldots x_n) \tag{2}$$

the properties of the function being such as enable any small change in utility to be stated as

$$dU = \sum_{i=1}^{n} \frac{\delta f}{\delta x_i} dx_i \tag{3}$$

Before any changes take place, the revenue apportioned to the ith good is

$$R_i = p_i x_i \qquad (i = 1 \ldots n) \tag{4}$$

so that any small change in this apportion-

ment may be described by

$$(5)\quad dR_i = p_i dx_i + x_i dp_i \qquad (i = 1 \ldots n)$$

Rewriting (5) in terms of dx_i and substituting into (3) yields

$$(6)\quad dU = \sum_{i=1}^{n} \left(\frac{\delta f}{\delta x_i} \bigg/ p_i \right) (dR_i - x_i dp_i)$$

However, the condition of utility maximization requires that

$$(7)\quad \frac{\delta f}{\delta x_i} \bigg/ p_i = \frac{\delta f}{\delta x_j} \bigg/ p_j = \lambda$$

$$= (\text{marginal utility of income})$$

$$(i, j = 1 \ldots n)$$

so that (6) reduces to

$$(8)\quad dU = \lambda \sum_{i=1}^{n} (dR_i - x_i dp_i)$$

$$= \lambda \left(dY - \sum_{i=1}^{n} x_i dp_i \right)$$

By comparing (8) with the considerations that led to (1), it is clear that the bracketed term $(dY - \sum_{i=1}^{n} x_i dp_i)$ can only be the exact income equivalent of a small utility change, as effected by a completely general set of changes in the parameters facing the consumer. Before we leave the general case for the time being, we should note a powerful result concerning changes that do not affect the individual's utility level. Since λ will not normally take the value zero, the statement

$$(9)\quad dU = 0 = \left(dY - \sum_{i=1}^{n} x_i dp_i \right)$$

provides concise information concerning movements along an indifference curve.

If the circumstances that bring about the utility change are of a restricted form, further simplifications of (8) are possible. Thus, if only income changes, all prices remaining constant, it follows from (8) that the income equivalent of the resulting change in utility is simply the change in income itself. Turning to utility changes brought about within the particular framework of a *ceteris paribus* change in the price of the ith good, we see that (8) reduces to

$$(10)\qquad dU = \lambda(-x_i dp_i)$$

Thus the income equivalent in this instance is the area to the left of the demand curve between the old and new price levels, a measure in agreement with that originally suggested by Dupuit. As we would expect, (10) tells us that an increase in price yields a negative income equivalent whereas a price fall provides a positive income equivalent consistent with a gain in utility. We may note that in the trivial case of a constant marginal utility of income, there is a direct numerical relationship between utility and areas to the left of the demand curve.

The question remains as to whether we may meaningfully evaluate the income equivalent of a large change in utility brought about by a greater price change than the one previously considered. Had the change in utility been brought about solely by a large change in income, no conceptual difficulty would arise from treating this income change as the sum of a series of continuous small changes. Bearing in mind that the income equivalent of a utility change effected by a small change in income is that change in income itself, we see that the sum of the income equivalents provides a monetary evaluation of benefits received that is in agreement with the actual change in income experienced. This would suggest that in so far as it is useful to talk of an individual being (say) N dollars better off as the result of a large change in income, so may we sum the income equivalents of utility changes effected by a series of continuous small price changes and conclude, if such a sum should also equal N dollars, that the individual is

N dollars better off as a result of the total price change.

On the basis that we regard the income equivalent of a large *ceteris paribus* price change as the sum of the income equivalents obtained by considering continuous small price changes, we may note that this concept is measured exactly by the area to the left of the demand curve, between the old and new price levels.

II. The Nature of the Compensating and Equivalent Variations

As stated earlier, a number of alternative expressions have been offered as measures of the 'income equivalent' of a utility change effected by a *ceteris paribus* price change. We shall consider two particular proxies that have received a good deal of attention in the literature, but at the same time we may note that any of the other proxies suggested could be submitted to a similar treatment. In both cases we shall limit ourselves to working through the result of a price fall for a normal good, although the expressions themselves apply equally to a price increase or decrease for any type of good.

Hicks originally appeared to believe that the desired income equivalent was equal to the sum of money (income) to be paid by a consumer when a price falls (received by him when a price rises), that would leave his general level of welfare unchanged.[6] Hicks called this the *compensating variation* definition of consumer's surplus, but following a comment by Henderson he recognized the approximation implicit in this measure and agreed that some account should be taken of an alternative measure, one that he chose to call the *equivalent variation* definition of consumer's surplus. For this concept we ask, what income would a consumer have to receive following a price fall (forego following a price rise) in order to be as well off at the old prices as he would be with his initial income at the new prices.

We may illustrate both of these concepts in Figure 1. Quantities of the ith good are measured horizontally along OX_i, while income (all other goods at constant prices) is measured on the vertical axis OY. With a fixed income Y_0 the budget constraint is given initially by Y_0P_1, and after the fall in the price of the ith good, by Y_0P_2. The indifference curves I_1 and I_2 show the utility levels that are optimal and feasible at the old and new price levels, respectively.

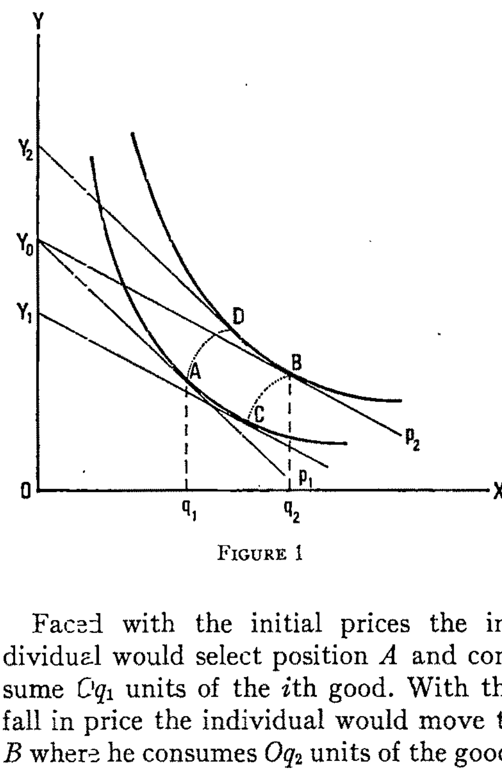

FIGURE 1

Faced with the initial prices the individual would select position A and consume Oq_1 units of the ith good. With the fall in price the individual would move to B where he consumes Oq_2 units of the good. What is required is the income equivalent of the utility change involved in the movement from A to B brought about by the price change. First we notice that the consumer could forego (Y_0-Y_1) of his income and still be as well off with the new

[6] See Hicks, pp. 40–41. The whole discussion in this paragraph should also be related to what Hicks has to say later, pp. 330–32.

prices as he was in the initial situation. The sum (Y_0-Y_1) thus provides the compensating variation proxy that we described above. Then again we can see that the consumer would need to have a total income of Y_2 to be as well off with the old prices as he would have been with the initial income and the new prices. The sum (Y_2-Y_0) is the equivalent variation measure that Hicks proposed. Both these expressions clearly describe an income equivalent of the utility difference between the indifference curves I_1 and I_2. Equally clearly the expressions are generally unequal, and a very brief consideration will show that neither expression describes the income equivalent of the utility change due to the price fall.

The key to the discrepancy is simply that any evaluation of the income equivalent of a given utility change will depend upon the value of the marginal utility of income along the path on which the evaluation takes place. Our assumption that the ith good is normal yields precise information as to the relevant values of the marginal utility of income, in particular that it will be greater at C than at either A or B whereas it must be less at D than at either of these terminal positions.[7] Thus the compensating variation will obtain the income equivalent of the utility difference between I_1 and I_2 taking into account the relatively high values of the marginal utility of income along the path (dotted) CB, while at the other extreme the equivalent variation will obtain an accordingly greater income equivalent of the same utility difference because of the lower values of the marginal utility of income of the path (dotted) AD.

Thus we can straightforwardly see why the expressions considered will generally take different values, and can only be approximations to the income equivalent of a utility gain associated with a price fall, which would be evaluated over the intermediate path AB. The magnitude of the differences between the compensating and the equivalent variations can easily be determined. Referring again to Figure 1, since the level of income is the same at both initial and final situations the sum of the income adjustments must equal zero along any path of adjustment between A and B that we may care to consider. Suppose we had undergone a series of price and income changes that first took us along the indifference curve I_1 from A to C, and then adjusted from C to B by income changes only. From equation (9) we see that the magnitude of the income changes along I_1 must be given by the integral $\int x_i dp_i$, evaluated over AC. This magnitude must equal that of the sum of the income adjustments from C to B, which is of course the compensating variation. A similar argument can be used to show that the equivalent variation will take the value of the integral $\int x_i dp_i$, evaluated along the indifference curve I_2 over the path DB. Since the price changes are the same in both integrals, it is the values of the x_i over the paths considered that determine relative magnitudes. Thus for vertically parallel indifference curves the expressions are equal. It also follows from these considerations that the difference between the expressions vanishes as the size of the total price change approaches zero.

III. Some Extensions of the Analysis

We have so far paid particular attention to the result that, for an individual, the income equivalent of a utility change effected by a *ceteris paribus* price change may be exactly measured by the area to the left of the relevant demand curve, between the initial and final price levels.

[7] To obtain these results it is only needed to notice that income is defined as "all other goods at constant prices," and that the marginal utility of income is given by the marginal utility of any good divided by its price.

This is a useful result, and amongst other things enables an appropriate interpretation to be made of the "Marshallian Triangle" that has received so much attention in the literature. Specifically we note that such areas do not refer to a utility gain achieved solely through the additional consumption of a specific good, and further that the *ceteris paribus* condition precludes the straightforward addition of such areas associated with different goods. However, treatment of the effects of a single price change on an individual represent a very limited application of our earlier analysis, and some more general results can easily be obtained. As we stated above, the result

$$dU = \lambda\left(dY - \sum_{i=1}^{n} x_i dp_i\right) \tag{8}$$

enables us to determine, for an individual, the income equivalent of a utility change associated with a completely general set of simultaneous small changes in prices and income. Again, it is clear from the form of (8), that market observations of income, price, and quantity will straightforwardly yield the net sum of the income equivalent of each individual's utility differences effected by any such changes as we may care to consider.[8] Noting that these aggregate measures may always be obtained, it is instructive to continue for the time being with analysis at the individual level.[9]

Returning to the general result (8), caution must be exercised in the treatment of greater than incremental changes. For example, suppose that we wish to compare an initial situation A and a final situation B characterized by substantially different price and income levels. It follows immediately from consideration of (8) that we have a necessary and sufficient condition for B to be preferred to A. This is that there should exist at least one path of small continuous price and income adjustments from A to B that yields a nonnegative sequence of incremental income equivalents, at least one element being positive. However our primary concern is to obtain a useful monetary evaluation of the utility difference between alternative situations, and the question we need to consider when we are dealing with large multiple price and income changes is how far we may still regard such an evaluation as being measured by the sum of successive incremental income equivalents. The complication that arises in such a case is that by allowing more than one variable to change we are admitting the possibility of an infinite number of adjustment paths between any two terminal situations. Since the marginal utility of income may take quite a different range of values along each different adjustment path, so will the sum of the income equivalents take on different magnitudes depending upon the precise path taken between the situations concerned. The unique determination of the income equivalent of a utility change effected by a large *ceteris paribus* price change is thus possible simply because such a framework defines a unique adjustment path.[10]

This path-dependence was first considered by H. Hotelling in 1938 and is the subject of a more recent and very thorough study by Eugene Silberberg (1972).[11] It

[8] There is broad agreement between this paper and a recent article by Arnold Harberger, who notes a similar result (1971), p. 789. However, the general approaches adopted are quite different.

[9] There are certain problems relating to the use of aggregate measures, and whenever we refer to such measures the reader should bear in mind certain necessary qualifications. For a discussion of these matters, see David Winch (1965), (particularly pp. 406–07).

[10] The reader should note, following equation (9), that this "path-dependence" only applies when the level of utility changes. Any movements along an indifference curve or surface must have a zero income equivalent, although if one leaves an indifference curve, and then returns to it, there is of course no reason why the same result should hold.

[11] Had more attention been paid to Hotelling's dis-

requires that we recognize the impossibility of associating a unique evaluation in money terms with the utility difference between any two situations. This is not to say that some evaluations of the income equivalent of a particular utility change are not a great deal more interesting than others. Indeed, with reference to Figure 1, consider any adjustments that would take us along the indifference curve I_1 from A to C and then from C to B solely as a result of income changes. The income equivalent evaluated along such a path would exactly equal Hicks' *compensating variation.*[12] An alternative path (AD by income changes, DB along I_1) would yield an income equivalent equal to the *equivalent variation*. Knowledge of the magnitude of these expressions could be useful for at least three reasons:

(i) for an individual, the sign of both these measures must be in agreement with the sign of the utility change concerned;

(ii) at the aggregate level, the sum of either of the individual *compensating* or *equivalent variations* will yield information as to whether compensations could be paid that would enable at least one individual to be made better off while leaving nobody worse off, although such information will sometimes be ambiguous;[13]

(iii) the Hicksian expressions can be regarded as providing sensible upper and lower limiting values of a monetary evaluation as the (net) benefits or losses involved.[14]

Consider now an income equivalent taken over a path of adjustment such that its value obtained is intermediate between the compensating and equivalent variations. The first criterion of usefulness is straightforwardly satisfied. In the second case our intermediate income equivalent would not be significantly different from zero in the ambiguous case, but could otherwise be generally expected to provide accurate information as to whether the stated compensations were possible. In the final case, the usefulness of having upper and lower limits would be related to the magnitude of the difference between the limits. In the substantial majority of cases where the marginal utility of income will not vary greatly over the range of the changes considered, the difference will be small and accordingly the intermediate income equivalent may be treated as a useful approximation to the desired monetary evaluation.

It remains to be noted that although neither of the Hicksian measures can be determined with any certainty in the aggregate form, it is a straightforward matter to determine the value of the (aggregate) income equivalent of a utility change evaluated along any adjustment path that might be observed or predicted to take place. Given the further point that for each individual most "actual" adjustment paths will be more direct than those that would yield the compensating or equivalent variations, we have every reason to expect that actual measures of the aggregate income equivalent would generally take values intermediate between the desired limiting expressions.

cussion of the matter (see particularly pp. 246–47), much of the confusion in the later literature might have been avoided. My own work was originally prepared in ignorance of Silberberg's paper and, although our approaches are quite different, certain similar conclusions are drawn.

[12] The adjustments along an indifference curve, yielding a zero utility change, must have a zero income equivalent. This also follows from result (9).

[13] It is quite possible for the sums of the individual compensating and equivalent variations to take different signs, given that there are both price falls and price rises.

[14] The two expressions may be regarded as evaluations of a fixed utility difference, taking into account the different (utility) purchasing power of money at the initial and final situations.

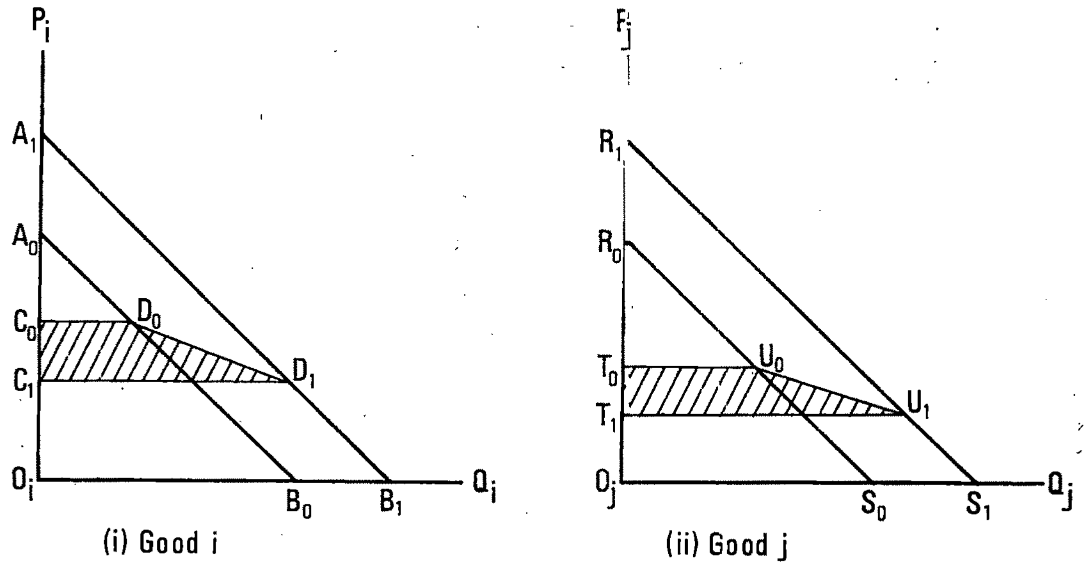

FIGURE 2

Having established reasons for our interest in the income equivalent of a utility change effected by a large change in more than one variable, it is only left for us to demonstrate the application of the analysis with a specific example. Suppose that the prices of the ith and jth goods change, income and all other prices held constant, so that (8) may be written

$$dU = \lambda(-x_i dp_i - x_j dp_j) \tag{11}$$

We illustrate the possible effects of a series of price changes of this type in Figure 2. Let A_0B_0 and R_0S_0 be the demand curves for the ith and jth goods, respectively, given the initial prices O_iC_0 and O_jT_0. If the prices change to O_iC_1 and O_jT_1, both demand curves will shift and we have taken the case where they both move to the right, A_0B_0 to A_1B_1 and R_0S_0 to R_1S_1. If we view these movements as the sum of many small movements along linear paths between D_0 and D_1 and between U_0 and U_1, respectively, the income equivalent of the change in total utility effected by these price changes is given by the sum of the two shaded areas $C_0C_1D_1D_0$ and $T_0T_1U_1U_0$. We can immediately see that for most practical purposes the variability of the income equivalent according to the path chosen is not going to be of any significant dimension. Indeed the normal processes of data observation or of prediction of the relevant price and quantity values will usually incorporate measurement errors far greater than the difference between the evaluations of the income equivalent taken along separate paths of price adjustment.[15]

Noting that path-dependence is usually of greater theoretical than practical importance, it is useful to consider briefly the evaluation of the income equivalent effected by changes that include a change in income itself. If income and the price of only the ith good are allowed to vary, (8) yields

$$dU = \lambda(dY - x_i dp_i) \tag{12}$$

which states that the income equivalent is the resulting sum of the change in income

[15] Most evaluations will lie between the Hicksian expressions, the difference between these latter terms being approximately $\Sigma dxdp$ for small changes.

itself, and an area that may be obtained by a treatment analogous to that used in the previous example. However, our interest in this case concerns the inclusion of the income change term. Suppose that instead of using the traditional model of consumer behavior where income is treated as an exogenous variable, we wished to allow an individual to substitute income for leisure. We might allow for this by writing the individual's utility function as

$$U = g(x_1 \ldots x_n, L) \tag{13}$$

and by defining income as

$$Y = (A - L)w \tag{14}$$

where A is the maximum possible time that may be allocated to the pursuit of income within the period considered, and w is the income forgone for an additional unit of leisure. To simplify the analysis, w as well as A may be treated as a constant. The reader may easily confirm that using this formulation the general result, equivalent of (8), is

$$dU = \lambda\left(\sum_{i=1}^{n} - x_i dp_i\right) \tag{15}$$

providing that income can only be changed by planned substitution between income and leisure. This result suggests that we should if possible distinguish between what we might call planned and unplanned variations in income, and only incorporate income changes of the second type into the evaluation of the income equivalent expression. As with the original model, no difficulty is presented in obtaining aggregate results, although the earlier cautionary comments still apply.

IV. Concluding Comments

In concluding our discussions of some of the applications and limitations of analysis based on the concept of consumer's surplus, it is appropriate to remind the reader of two points. First, for reasons stated earlier, we have dwelt very little on some of the problems associated with the aggregation of our results. Secondly, although we have talked of aggregate benefits or losses, these have only been considered in respect of consumption behavior and have ignored the shadow concept of producer's surplus.[16] We have done this to avoid repeating much that has appeared in the literature before, but our position concerning the second point should be quite clear. Any analysis of the type presented here, if used to evaluate benefits or losses accruing to the community as a whole, must incorporate the appropriate producer's surplus effects, and this latter concept should be treated with similar caution to that exercised in respect of our treatment of consumer's surplus.[17]

Notwithstanding these comments we would summarize the strong conclusions that can be drawn from this paper. The income equivalent of a utility change effected either by a *ceteris paribus* price change, or by small multiple price and income changes, is an entirely valid construct and may be measured accurately from observations of price, income, and quantity. The income equivalent of a utility change effected by large multiple price and income changes is a useful construct, and may also be measured accurately from observable data. Providing economists understand the concepts involved and the limitations and restrictions

[16] The recent 1971 survey article by J. M. Currie et al. provides a comprehensive summary of the relevant literature.

[17] The inclusion of producer's surplus effects may well reduce the importance of path-dependency, since its influence will often be counteracted between the two "surplus" measures. To illustrate this, consider the imposition of a sales tax on a particular good. Alternative adjustment paths can be generated by considering simultaneous variations in income, noting that an increase in income will generally shift the demand curve to the right and the supply curve to the left.

implicit in their use, the notions of consumer's and producer's surplus have a wide range of useful and illuminating applications in the fields of economic analysis and policy.

Monetary and Fiscal Policy in a Two-Sector Aggregative Model

By DALE W. HENDERSON AND THOMAS J. SARGENT*

This paper analyzes the short-term influences exerted by monetary and fiscal policies in a two-sector macroeconomic model. The model is not new, but is identical with Hirofumi Uzawa's two-sector model, except that we have added markets in stocks of three paper assets, money, bonds, and equities. Adding these three markets produces essentially the same model used by Duncan Foley and Miguel Sidrauski to describe long-run behavior, given certain government policies. While the model studied here is virtually indistinguishable from theirs, we use the model to investigate very different questions. Our method of analysis is best characterized as "Keynesian" in two important senses. First, we analyze events over the "short run," a period of time so short that it is legitimate to assume that capital is fixed, even in the face of a nonzero rate of net investment. Where time is viewed as passing continuously, as it shall be here, this definition means that short-run occurrences are those that are assumed to take place at a point in time. Second, for the most part we assume that the money wage rate is rigid at any moment, the kind of assumption that it is necessary to make in order to build a model in which unemployment is possible, and in which it is interesting to investigate the short-run effects on employment and output of alternative monetary and fiscal policies. We assume only that the money wage rate is fixed at a point in time, which is compatible with having the money wage change over time, as long as it does so continuously. The money wage might well respond to the imposition of disturbances on the economy; our assumption permits such adjustments to occur over time, but rules out any instantaneous adjustments in money wages.

An important characteristic of the model is that it includes a perfect market in existing stocks of physical capital, a market in which there are no transactions costs either for buyers or sellers of capital.[1] By buying or selling capital in this market, individual firms are able to obtain instantaneously the quantities of capital they desire to hold at each moment. Monetary and fiscal policies work by introducing disturbances in this market, disturbances that ultimately affect the prices of capital goods and consumption goods, thereby affecting the number of workers firms want to employ at a fixed money wage. Thus, in our model, the market in existing stocks of physical capital occupies a critical role in transmitting monetary and fiscal policy influences. In contrast, the standard Keynesian model assumes no market in existing physical capital, presumably because of very high transactions costs. Such an assumption rationalizes the Keynesian flow investment demand function and makes the demand func-

* Member of the staff of the Board of Governors of the Federal Reserve System and member of the department of economics of the University of Minnesota, respectively. Sargent's work on this paper was partially supported by the Federal Reserve Bank of Minneapolis. The Federal Reserve System is in no way responsible for the conclusions of this paper.

[1] By transactions costs we mean a complete measure of the costs of transacting, including brokerage fees, bid-ask price spreads, search costs, dismantling and installation costs, etc.

tions for current output critical determinants of output.[2]

In our model, monetary policy is generally extremely potent in affecting output and employment. Of course, monetary policy also has important effects on these same variables under some sets of assumptions in the standard Keynesian model. However, in contrast with the Keynesian model, our model implies that an increase in the flow of government expenditures may either increase or reduce output and employment, depending upon the relative capital intensities of the two sectors and some other conditions. Moreover, whatever their direction, the effects of an increase in government expenditures are smaller the more similar are the capital intensities of the two sectors. Basically our model is an extension of James Tobin's Dynamic Aggregative Model, one that collapses to a version of Tobin's model when the production functions in the two sectors are assumed to be identical. When the production functions are identical, variations in government expenditures and in "autonomous" consumption have no effects on output and employment at a point in time, just as is true in Tobin's model. The "monetarist" implications of our model are ultimately attributable to the presence of the market in existing capital.

Section I contains a description of the behavior of firms, households, and the government. Section II describes the properties of the model, while our conclusions are presented in Section III.

[2] It seems clear that the formal model described by J. M. Keynes in the *General Theory* contains a market in existing stocks of capital goods. His discussions of the marginal efficiency of capital and the stock market (chs. 11 and 12) make this clear. The fact that the standard Keynesian model rules out trading in existing stocks of capital is perhaps the key departure that the Keynesians made from the formal model of the *General Theory*. For a discussion that attempts to highlight the important implications of what characteristics are assigned to the market in existing capital, see Sargent and Wallace.

I. Description of Firms, Households, and the Government

Firms

Firms in sector 1 use capital and labor to produce capital goods, those in sector 2 use the same kinds of capital and labor to produce consumer goods. Individual firms within each sector are faced with identical production functions. The price of capital goods is p_1p, while the price of consumer goods is p. Firms in both sectors are assumed to hire the amounts of capital and labor that maximize their profits at each moment. At each moment they can hire all the labor they want at the fixed money wage w, and they can purchase or sell all the capital they wish to at the price of capital, p_1p (alternatively, we might just as well assume that firms can rent all the capital they wish at an appropriate rental). Firms are assumed to issue no bonds, financing capital expansion by issuing equities.[3] However, we shall assume that when their yields are equal, government bonds and equities are perfect substitutes as far as wealth-holders are concerned, so that in equilibrium the nominal yield on equities must equal the nominal yield on government bonds, r. This assumption implies that r is the appropriate discount rate to be used in calculating the firm's present value; equivalently, r is the market interest rate that belongs in the cost of capital used to calculate the firm's profits.[4] Firms are assumed to retain no

[3] Our assumption that firms issue no bonds is not restrictive. For as Franco Modigliani and Merton Miller have shown, the pertinent cost of capital is the yield on equities for firms which have no bonds outstanding. Moreover, even if firms were permitted to have bonds outstanding, our assumption that wealth-holders regard bonds and equities as perfect substitutes would guarantee that the yield on a firm's equities would not depend on the volume of bonds it has outstanding. See Modigliani and Miller, in particular their "proposition II."

[4] See Dale Jorgenson for a demonstration of the equivalence of profit maximization and present value maximization, given a properly defined cost of capital.

earnings, paying out all profits in the form of dividends.

Outputs in sectors 1 and 2, Y_1 and Y_2, respectively, are determined by the production functions

$$Y_1 = Y_1(K_1, N_1) \tag{1}$$

$$Y_2 = Y_2(K_2, N_2) \tag{2}$$

where N_i is employment in the ith sector and K_i is capital in the ith sector. We assume that each production function is linearly homogeneous in K_i and N_i and has positive though diminishing marginal products, and positive cross-partial derivatives, i.e., $Y_{iN}>0$, $Y_{iK}>0$, $Y_{iNN}<0$, $Y_{iKK}<0$, $Y_{iKN}>0$, where Y_{iN} is the marginal product of labor in sector i, etc.

We assume that capital depreciates exponentially at the same rate δ in both sectors. Households and firms in both sectors expect that both the money wage, w, and the prices of consumer and capital goods will rise at the rate π, a magnitude that we treat as a parameter in the exercises below.[5] The government is assumed to levy a "profits" tax on each firm's net cash flow. The latter exceeds economic profits by the real yield on equities, $r-\pi$, multiplied by the value of the firm's capital. The marginal profits tax rate is t_K.

On these assumptions, the after-tax profits of the typical firm in sector 1, the capital goods sector, are[6]

$$\textstyle\sum_1 = pp_1Y_1(K_1, N_1) - wN_1 - (r+\delta-\pi)p_1pK_1 - t_K[p_1pY_1(K_1, N_1) - wN_1 - \delta p_1pK_1]$$

Rearranging the first-order conditions for profit maximization, we obtain

$$Y_{1N} = \frac{w}{p_1p} \tag{3}$$

$$Y_{1K} = \delta + \frac{1}{1-t_K}(r-\pi) \tag{4}$$

After-tax profits in sector 2 are

$$\textstyle\sum_2 = pY_2(K_2, N_2) - wN_2 - (r+\delta-\pi)p_1pK_2 - t_K[pY_2(K_2, N_2) - wN_2 - \delta p_1pK_2]$$

Upon rearranging the first-order conditions for profit maximization, we obtain

$$Y_{2N} = \frac{w}{p} \tag{5}$$

$$Y_{2K} = p_1\left[\delta + \frac{1}{1-t_K}(r-\pi)\right] \tag{6}$$

Equations (1) through (6) are assumed to hold at each moment in time, any violations of the equations being eliminated immediately by firms' trading in the markets for capital and labor.

Generally, we will take advantage of the linear homogeneity of (1) and (2) and write them in the intensive form

$$\frac{Y_i}{N_i} = Y_i\left(\frac{K_i}{N_i}, 1\right) = f_i(k_i)$$

where

$$k_i = \frac{K_i}{N_i}$$

In this notation, the marginal products of labor and capital are $Y_{iN}=f_i(k_i)-k_if_i'(k_i)$ and $Y_{iK}=f_i'(k_i)$. Substituting these expressions for the marginal products in equations (3) through (6) yields the form of the equations that it will be convenient to manipulate in Section II.

[5] It is necessary to treat π as a parameter at any moment in order to close the model. Otherwise the model would possess fewer equations than variables it must determine at a point in time. See Neil Wallace.

[6] It is easy to verify that maximizing profits so defined is equivalent to maximizing the firm's present value,

$$V(K_1, N_1, \dot{K}_1, t) = \int_0^\infty e^{-rt}\{(1-t_K)[p_1p(t)Y_1(K_1(t), N_1(t)) - w(t)N_1(t) - p_1p(t)\delta K_1(t)] - p_1p(t)\dot{K}_1(t)\}dt$$

where $w(t)$ and $p(t)$ are assumed to be expected to follow the paths

$$w(t) = we^{\pi t}$$
$$p(t) = pe^{\pi t}$$

The description of the factor markets is completed by noting that the total supply of capital, K, is fixed at a point in time. The assumptions that Y_{1K} and Y_{2K} are greater than zero, that there is a perfect market in existing capital, and that p_1, p, and r are flexible instantaneously imply that capital is fully employed at each moment,

$$K = K_1 + K_2 \tag{7}$$

However, the fact that the money wage is fixed means that labor need not be fully employed.

Notice that since households view bonds and equities as perfect substitutes, the value of equities issued by the capital goods industry, V_1, is the capitalized value of dividends, the appropriate capitalization rate being the bond rate, r, minus the anticipated rate of inflation:

$$V_1 = \frac{(1 - t_K)(pp_1 Y_1 - wN_1 - \delta p_1 p K_1)}{r - \pi}$$

which, by the first-order conditions for profit maximization and the linear homogeneity of the production function, equals $p_1 p\ K_1$. Similarly, the value of outstanding equities issued by the consumer goods industry, V_2, equals $p_1 p\ K_2$.

The Government

As liabilities the government has outstanding stocks of money with nominal value M and variable-interest-rate government bonds with nominal value B. The bonds are like savings deposits, their value remaining fixed in the face of fluctuations in the interest rate. The nominal yield on money is fixed at zero, while the nominal yield on bonds, r, is determined in the market. At a point in time the government conducts open-market operations subject to the constraint $dM = -dB$.

The government levies an income tax with marginal rate t_Y and a profits tax with marginal rate t_K. The base for the income tax is personal income, which consists of wage returns to labor, dividends, and nominal capital gains on equity. In real terms, laborers receive (w/p) $(N_1 + N_2)$, while stockholders receive in dividends

$$(1 - t_K)\left(p_1 Y_1 - \frac{w}{p} N_1 - \delta p_1 K_1\right) + (1 - t_K)\left(Y_2 - \frac{w}{p} N_2 - \delta p_1 K_2\right)$$

which, by the first-order conditions for profit maximization and the linear homogeneity of the production functions, equals $(r-\pi)p_1K$. Nominal capital gains on equities are expected to occur at the rate $\pi p_1 p K$. Thus, individuals expect to be paying income tax at the real rate

$$T_Y = t_Y\left[\frac{w}{p} N + (r - \pi)p_1 K + \pi p_1 K\right]$$

where $N = N_1 + N_2$. Notice that the after-tax real yield on equities equals $(1-t_Y)r-\pi$.

Real revenues from the profits tax are

$$T_K = t_K\left[p_1 Y_1 - \frac{w}{p} N_1 - \delta p_1 K_1\right] + t_K\left[Y_2 - \frac{w}{p} N_2 - \delta p_1 K_2\right]$$

which, by the first-order conditions for profit maximization and the linear homogeneity of Y_1 and Y_2, equals $(t_K/(1-t_K))$ $(r-\pi)p_1K$.

In real terms, total tax receipts net of transfer payments are given by $T = T_0 + T_Y + T_K$ where T_0 represents real tax receipts net of transfer payments that do not depend on personal income or business profits.[7]

Total real government expenditures

[7] Notice that there is a double tax on dividends.

denominated in units of consumer goods, G, are composed of real expenditures on capital goods, p_1g_1, and real expenditures on consumer goods, g_2. We will assume that if g_1 exceeds zero, the government simply stores or destroys the capital it is purchasing, neither renting it to private firms nor using it in production itself.[8]

The government makes its expenditure decisions subject to the flow budget constraint

$$G = T + \frac{DM}{p} + \frac{DB}{p}$$

where D is the operator d/dt. The government can finance a deficit by issuing money or bonds at some rate per unit time.

Households

Households own money, bonds, and equities. The real value of households' wealth is thus

$$W = \frac{M}{p} + \frac{B}{p} + p_1K$$

Portfolio balance for households is satisfied when the supply of real balances equals the demand,

$$(8) \quad \frac{M}{p} = m[Y, (1 - t_Y)r], m_1 > 0, m_2 \leq 0$$

where Y is real GNP, that is

$$(9) \quad Y = p_1Y_1 + Y_2$$

[8] We make this last assumption only for the sake of simplicity. Allowing the government to rent out the capital it buys to firms would require relatively minor changes in some definitions and accounting relationships. The rate of accumulation of capital to be used in production would be higher with government rental of capital. However, none of the conclusions of the comparative statics analysis presented below would be altered. Permitting the government to engage in production would involve the addition of a third production sector, a complication which we wish to avoid. A model in which the government purchases capital and labor, using them to produce a flow of government services, is discussed in Sargent and Wallace.

The demand for real money balances is assumed to depend on real GNP, which we take as a proxy for the rate of transacting in the economy, and the after-tax nominal rate of interest, which is the differential between the anticipated return on money holding, $-\pi$, and the anticipated return to bond holding, $(1-t_Y)r-\pi$. Omitting wealth from equation (8) amounts to assuming that households desire to hold any increment in wealth entirely in the form of bonds or equities.[9]

We will usually assume that households' demand for consumption goods is governed by

$$C = c(Y - \delta p_1K - T), \quad 1 > c_Y > 0$$

where

$$Y - \delta p_1K - T = \frac{w}{p}N + (r-\pi)p_1K - T_Y - T_0$$

is householders' real disposable income according to national accounts concepts, although we will also indicate how the model works when more general forms are assumed for the consumption function.[10]

For the economy to be in equilibrium, households' and the government's demands for consumer goods must sum to supply:

$$(10) \quad Y_2 = c(Y - \delta p_1K - T) + g_2$$

Expenditures on consumption goods are

[9] Our assumptions imply that the demand by the public for bonds and equities is given by

$$\left(\frac{B+V}{p}\right)^D = a[Y, (1 - t_Y)r, W],$$

$$a_1 = -m_1, \quad a_2 = -m_2, \quad a_3 = 1$$

where $V = V_1 + V_2$ is the total nominal value of the equities issued by both industries.

[10] One example of such more general forms is

$$C = c\left[Y - \delta p_1K - T - \pi\left(\frac{M+B}{p}\right), (1-t_Y)r - \pi, W\right]$$

$$c_1 > 0, \quad c_2 < 0, \quad c_3 > 0$$

where $\pi(M+B)/p$ is wealth holders' perceived capital loss due to anticipated inflation on government liabilities of fixed nominal value.

assumed to lead to no accumulation of stocks. Instead, consumption goods are assumed to be perfectly perishable.

Other Relationships

Equations (1) through (10) determine the position of the economy at a point in time. In addition to these ten equations, the model contains a few other equations which, while they do not enter into the determination of momentary equilibrium at any particular point in time, are important because they govern the evolution of the system over time. In particular, the economy's rate of capital accumulation is governed by $DK = Y_1 - \delta K - g_1$.

We are assuming that the money wage is rigid at any moment. This assumption is compatible with the existence of a "Phillips curve," for example,

$$\frac{Dw}{w} = \gamma(N, \pi), \qquad \gamma_N > 0, \qquad \gamma_\pi > 0,$$

provided that the implied value of Dw/w is always finite.

Next, we need an equation that explains how expectations of inflation are revised with the passage of time. The "adaptive-expectations" scheme

$$D\pi = \alpha\left(\frac{Dp}{p} - \pi\right), \qquad \infty > \alpha > 0$$

where Dp is a left-hand derivative, is compatible with our assumption that at any moment in time π is fixed.

Finally, we have assumed that firms finance investment with equities. This implies that firms issue equities at a rate with nominal value $DV = p_1 p DK$.

Relationships like these four occupy important roles in determining the behavior of the model over time. However, since this paper is dedicated to the "static" or point-in-time analysis of our model, these equations will be of little concern in what follows.

II. Behavior of the Model

We find it convenient to rewrite the system formed by equations (1) through (10) in the following way:

$$Y_2 = c(Y - T - p_1\delta K) + g_2 \tag{11}$$

$$Y = p_1 Y_1 + Y_2 \tag{12}$$

$$Y_1 = K_1/\beta_1 \tag{13}$$

$$\beta_1 = k_1/f_1(k_1) \tag{14}$$

$$Y_2 = K_2/\beta_2 \tag{15}$$

$$\beta_2 = k_2/f_2(k_2) \tag{16}$$

$$K = K_1 + K_2 \tag{17}$$

$$\frac{M}{p} = m[Y, (1 - t_Y)r] \tag{18}$$

$$f_1'(k_1) = \epsilon \tag{19}$$

$$f_1(k_1) - f_1'(k_1)k_1 = \frac{1}{p_1}\frac{w}{p} \tag{20}$$

$$f_2'(k_2) = p_1\epsilon \tag{21}$$

$$f_2(k_2) - f_2'(k_2)k_2 = \frac{w}{p} \tag{22}$$

$$\epsilon = \delta + \frac{r - \pi}{(1 - t_K)} \tag{23}$$

This is a system of thirteen equations in the thirteen variables Y_1, Y_2, Y, K_1, K_2, k_1, k_2, p, p_1, r, β_1, β_2, and ϵ. The parameters of the model are g_2, T, t_Y, t_K, w, M, π, and K. Our analysis will be static, no time being permitted to pass as we move from one position to another.[11] The variables of the model are assumed to adjust instantaneously in response to the imposition of a disturbance in the form of a change in one or more of the model's parameters.

Our strategy for solving the model is straightforward. We reduce equations (11) through (23) to a pair of relationships

[11] Notice that on our assumptions neither the government's flow budget constraint nor the equation describing the economy's rate of capital accumulation enters as a determinant of the positions of our variables at a particular point in time.

involving Y, real gross national product measured in terms of the consumption good, and ϵ, the gross return to capital in terms of capital goods, and the parameters g_2, T, t_Y, t_K, w, M, π, and K. The first relationship, called the MM schedule, gives the pairs of Y and ϵ which assure portfolio balance for wealth holders. To obtain this relationship we use equations (18), (23), and the profit maximization subsystem, equations (19) through (22). The pairs of ϵ and Y on the MM schedule assure portfolio balance for wealth holders and are compatible with profit maximization, but there is no guarantee that an ϵ and Y pair along the MM curve will result in equality between the stock of capital in existence and the stock firms would like to hold.

The second relationship gives the pairs of ϵ and Y which assure that the market for existing capital is cleared. To obtain this relationship, called the KK schedule, we use all the equations except (18). Pairs of ϵ and Y along this schedule are compatible with profit maximization and assure that firms are content to hold just the existing capital stock; however, wealth holders may not be satisfied with their portfolios at particular Y and ϵ pairs on the KK schedule. The $\epsilon - Y$ pair at the intersection of the KK and MM curves assures both portfolio balance and equilibrium in the market for existing capital.

Some Preliminary Relationships

The first step in obtaining the MM and KK schedules is to use the profit maximization subsystem, equations (19) through (22), to obtain expressions for k_1, k_2, and p_1 in terms of ϵ and an expression for p in terms of ϵ and w. Since $f_1''(k_1)<0$ we can invert (19) to obtain:

$$(24)\quad k_1 = k_1(\epsilon) \quad \text{where} \quad k_{1\epsilon} = \frac{1}{f_1''} < 0$$

We know from profit maximization that the ratio of the marginal product of labor to the marginal product of capital in both industries must equal the wage-rental ratio, which we denote by ω. Thus dividing (20) by (19) and (22) by (21) we have the following:

$$\frac{f_1(k_1)}{f_1'(k_1)} - k_1 = \omega$$

$$\frac{f_2(k_2)}{f_2'(k_2)} - k_2 = \omega$$

$$\omega = \frac{w}{p_1 p\epsilon}$$

Setting the ratios of marginal products in the two industries equal and using (24) we obtain:

$$\frac{f_1[k_1(\epsilon)]}{f_1'[k_1(\epsilon)]} - k_1(\epsilon) = \frac{f_2(k_2)}{f_2'(k_2)} - k_2$$

This equation defines a relationship between k_2 and ϵ. Differentiating and rearranging,[12] we arrive at the following:

$$(25)\qquad k_2 = k_2(\epsilon),$$

$$k_{2\epsilon} = \frac{p_1^2}{f_2''}\,\frac{f_1}{f_2} < 0$$

The economics behind equation (25) is straightforward. Raising the gross rate of return on capital causes the capital-labor ratio in the capital goods industry, k_1, to fall. This decline in k_1 means that the wage-rental ratio, ω, must fall. With a decrease in ω, the ratio of the marginal product of labor to the marginal product of capital in the consumption goods in-

[12]
$$\frac{f_1 f_1''}{(f_1')^2} k_{1\epsilon} d\epsilon = -\frac{f_2 f_2''}{(f_2')^2} dk_2$$

$$dk_2 = \frac{1}{f_2''}\,\frac{f_1}{f_2}\,\frac{(f_2')^2}{(f_1')^2} d\epsilon$$

$$dk_2 = \frac{p_1^2}{f_2''}\,\frac{f_1}{f_2} d\epsilon$$

Thus we can write (25).

dustry must fall in order to reestablish equilibrium, and in order for the ratio of marginal products to fall, the capital-labor ratio in the consumption goods sector, k_2, must decline.

Perfect competition and constant returns to scale imply that each firm in each industry and hence each industry as a whole must earn zero economic profits. We write this condition in intensive form:

$$pp_1f_1 - w - pp_1\epsilon k_1 = 0$$

$$pf_2 - w - pp_1\epsilon k_2 = 0$$

Differentiating these two equations, employing (19) and (21), and rearranging we obtain a relationship between p_1 and ϵ:[13]

$$(26) \qquad p_1 = p_1(\epsilon)$$

where

$$p_{1\epsilon} = \frac{p_1^2}{f_2}(k_1 - k_2) \gtrless 0 \quad \text{as} \quad k_1 \gtrless k_2$$

The effect of an increase in ϵ on p_1 depends upon the relative capital intensities of the two industries. If, as is often assumed, the consumption good is relatively more capital intensive than the capital good, the price of the capital good in terms of the consumption good falls as the real return on capital rises. More generally, we have seen that raising ϵ lowers the wage-rental ratio so that in order for both industries to continue just to cover costs, the industry which uses relatively more capital must have the price of its good rise relative to the price of the good which requires relatively less capital.

Finally, substituting (25) into (22) we have:

$$f_2[k_2(\epsilon)] - f_2'[k_2(\epsilon)]k_2(\epsilon) = \frac{w}{p}$$

Differentiating and rearranging, we obtain:[14]

$$(27) \qquad p = p(\epsilon, w)$$

where

$$p_\epsilon = \frac{p^2p_1^2}{w}\frac{f_1k_2}{f_2} > 0, \quad p_w = \frac{p}{w} > 0$$

The economics embodied in equation (27) is as follows. We know that raising ϵ lowers the capital-labor ratio in the consumption goods industry. This decline lowers the marginal product of labor in that industry, so the real wage in terms of consumption goods must fall. With w fixed, the real wage can fall only if p rises. If w is increased and ϵ stays constant, p must rise in order to keep the real wage the same.

Two other relationships are useful at a later stage. Substituting (24) into (14),

[13] $$(p_1f_1 - p_1\epsilon k_1)dp + (pf_1 - p\epsilon k_1)dp_1 + [(pp_1f_1' - pp_1\epsilon)k_{1\epsilon} - pp_1k_1]d\epsilon - dw = 0$$
$$(f_2 - p_1\epsilon k_2)dp - p\epsilon k_2dp_1 + [(pf_2' - pp_1\epsilon)k_{2\epsilon} - pp_1k_2]d\epsilon - dw = 0$$

Using (19) and (21) and the zero profit condition these two equations become

$$\frac{w}{p}dp + \frac{w}{p_1}dp_1 - pp_1k_1d\epsilon - dw = 0$$
$$\frac{w}{p}dp - \left(\frac{pf_2 - w}{p_1}\right) - pp_1k_2d\epsilon - dw = 0$$

Setting the left-hand sides of these two equations equal to one another we obtain:

$$\frac{w}{p}dp + \frac{w}{p_1}dp_1 - pp_1k_1d\epsilon - dw = \frac{w}{p}dp - \frac{pf_2 - w}{p_1}dp_1 - pp_1k_2d\epsilon - dw$$

$$dp_1 = \frac{p_1^2}{f_2}(k_1 - k_2)d\epsilon$$

Thus we can write (26).

[14] $$-f_2''k_{2\epsilon}k_2d\epsilon = \frac{1}{p}dw - \frac{w}{p^2}dp$$
$$dp = \frac{p^2p_1^2}{w}\frac{f_1k_2}{f_2}d\epsilon + \frac{p}{w}dw$$

Thus we can write (27).

we have a relationship between the capital-output ratio and ϵ:

$$\beta_1 = \frac{k_1(\epsilon)}{f_1[k_1(\epsilon)]}$$

Differentiating and rearranging, we obtain:[15]

$$(28) \qquad \beta_1 = \beta_1(\epsilon)$$

where

$$\beta_{1\epsilon} = \frac{w}{pp_1}\,\frac{1}{f_1^2}\,k_{1\epsilon} < 0$$

Similarly, (16) and (25) yield:

$$(29) \qquad \beta_2 = \beta_2(\epsilon) \text{ where } \beta_{2\epsilon} = \frac{1}{f_2^2}\,\frac{w}{p}\,k_{2\epsilon} < 0$$

In both industries, raising ϵ lowers the capital-output ratio.

The MM Schedule

We are now prepared to derive the *MM* schedule, which shows the pairs of ϵ and Y which are compatible with portfolio balance given that the conditions for profit maximization are satisfied. We use (23) to obtain an expression for the nominal rate of interest in terms of the real gross rate of return ϵ,

$$(30) \qquad r = (1 - t_K)(\epsilon - \delta) + \pi$$

This equation states that the nominal interest rate must be equal to the after-tax real rate of return net of depreciation plus the anticipated rate of inflation. Substituting (27) and (30) into (18), we obtain the *MM* schedule,

$$(31) \qquad \psi(Y, \epsilon; M, t_Y, t_K, \pi) = m[Y, (1 - t_Y)\{(1 - t_K)(\epsilon - \delta) + \pi\}] - \frac{M}{p(\epsilon, w)} = 0$$

We view the *MM* schedule as giving ϵ as a function of Y and the relevant parameters, an appropriate view as long as $\psi_\epsilon \neq 0$. Differentiating (31) and rearranging, we arrive at an expression which allows us to determine both the slope of the *MM* schedule and the shifts in the schedule that are caused by changes in the parameters of the model:

$$(32) \qquad d\epsilon = -\frac{m_1}{\psi_\epsilon}\,dY + \frac{\frac{1}{p}}{\psi_\epsilon}\,dM - \frac{\left(\frac{M}{p^2}\right)p_w}{\psi_\epsilon}\,dw + \frac{m_2 r}{\psi_\epsilon}\,dt_Y - \frac{m_2(1 - t_Y)}{\psi_\epsilon}\,d\pi + \frac{m_2(1 - t_Y)(\epsilon - \delta)}{\psi_\epsilon}\,dt_K$$

$$\psi_\epsilon = \frac{M}{p^2}\,p_\epsilon + m_2(1 - t_Y)(1 - t_K)$$

The signs of the slope of the *MM* schedule and of the expressions for the effects of shifts in the parameters depend crucially on ψ_ϵ. Given the way we have written (31), ψ_ϵ gives the effect of an increase in ϵ on the excess demand for real balances, *ceteris paribus*. Raising ϵ has two offsetting effects on the excess demand for real balances. On the one hand raising ϵ raises r, which makes wealth holders desire smaller real balances. This effect, which we shall call the interest elasticity of demand effect (*IEDE*), tends to reduce excess demand for real balances and is represented by $m_2(1-t_Y)\,(1-t_K)$. On the other hand, raising ϵ means that p must

[15] $$d\beta_1 = \frac{f_1 - f_1' k_1}{f_1^2}\,k_{1\epsilon}d\epsilon$$

$$d\beta_1 = \frac{w}{pp_1}\,\frac{1}{f_1^2}\,k_{1\epsilon}d\epsilon$$

Thus we can write (28).

rise if the profit maximization conditions are to continue to be satisfied. This increase in p reduces the supply of real balances. This effect, which we shall call the profit maximizing supply effect (*PMSE*), and which is represented by $(M/p^2)p_\epsilon$, tends to create an excess demand for real balances. If the *IEDE* is stronger ($\psi_\epsilon<0$), then an increase in ϵ leads to a net decline in the excess demand for real balances and if the *PMSE* is stronger ($\psi_\epsilon>0$), to a net increase in excess demand. We call the case when the *IEDE* is stronger the interest elastic case (*IEC*) and the case when the *PMSE* is larger the interest inelastic case (*IIC*). We believe that the *IEC* is the more important of the two cases, so we will explore only this case in detail. However, we will supply the reader with all the ingredients for a full analysis of the interest inelastic case.

The slope of the *MM* curve and the effect on the position of the *MM* curve of changes in the parameters can now be easily determined. As Y is increased, wealth-holders wish to hold more real balances, creating an excess demand for real balances. Whether ϵ must rise or fall depends upon whether raising ϵ creates an excess supply or demand for real balances when Y is constant. In the *IEC*, ϵ must rise in order to reestablish portfolio balance. This case is shown in Figure 1.

From (31) we have:

$$\left.\frac{d\epsilon}{dY}\right|_{MM}^{IEC} = -\frac{m_1}{\psi_\epsilon} > 0$$

Of course, in the interest inelastic case the *MM* schedule slopes downward.

Our *MM* schedule somewhat resembles the textbook *LM* schedule.[16] The primary difference is that we have insisted that the profit maximization conditions be fulfilled at every point on the *MM* curve. This requirement is not imposed when deriving the usual version of the *LM* curve. It is our new requirement which has raised the ambiguity about the slope of the *MM* curve.

[16] For example, see Martin Bailey.

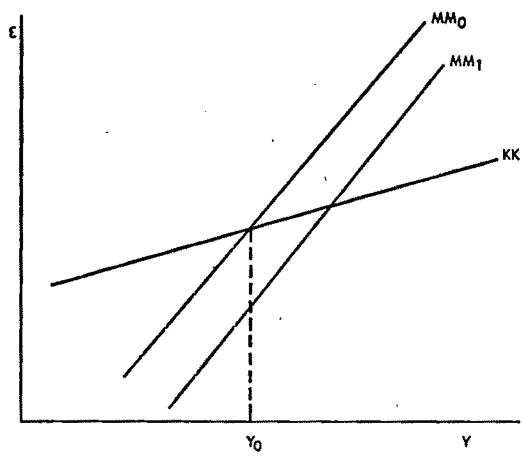

FIGURE 1

We now consider the effects of shifts in the parameters on the *MM* curve.

An increase in the money supply

With Y fixed an increase in M leads to an excess supply of real balances, so in the *IEC* we must have a fall in ϵ in order to reduce the nominal rate so that portfolio balance can be reestablished:

$$\left.\frac{d\epsilon}{dM}\right|_{MM,dY=0}^{IEC} = \frac{\frac{1}{p}}{\psi_\epsilon} < 0$$

Thus an increase in the money supply shifts *MM* down, say from MM_0 to MM_1 in Figure 1.

An increase in the money wage

An increase in the money wage rate, w, means that p must be increased for profit maximization. An increase in p leads to an excess demand for real balances at the original ϵ, so with Y fixed in the *IEC*, ϵ

must rise in order to raise the nominal rate so that portfolio balance can be reestablished:

$$\left.\frac{d\epsilon}{dw}\right|_{MM,dY=0}^{IEC} = -\frac{\frac{M}{p^2}p_w}{\psi_\epsilon} > 0$$

An increase in w shifts the MM curve upward, say from MM_1 to MM_0 in Figure 1.

An increase in t_Y

If there is an increase in t_Y with total tax revenues being held constant by an alteration in T_0, the attractiveness of the return producing assets, bonds and equities, is reduced. At the original ϵ, excess demand for money results, so with Y constant we must have an increase in ϵ in the interest elastic case:

$$\left.\frac{d\epsilon}{dt_Y}\right|_{MM,dY=0}^{IEC} = \frac{m_2 r}{\psi_\epsilon} > 0$$

The MM schedule thus shifts upward with a rise in t_Y.

An increase in anticipated inflation

A rise in the anticipated rate of inflation, π, means that equities become more attractive relative to money, which earns no nominal return, and bonds, the returns from which are fixed in money terms. With ϵ fixed, the nominal rate r rises by $d\pi$, but with Y fixed there will be an excess supply of real balances at this new nominal rate. In the interest elastic case, there must be a decline in ϵ large enough to lower the nominal rate enough to remove the excess supply:

$$\left.\frac{d\epsilon}{d\pi}\right|_{MM,dY=0}^{IEC} = -\frac{m_2(1-t_Y)}{\psi_\epsilon} < 0$$

An increase in π shifts the MM curve down. Given Y, the nominal rate ends up lower after an increase in π, as can be seen from the following expression derived by differentiating (30):

$$\left.\frac{dr}{d\pi}\right|_{MM,dY=0}^{IEC} = \left[1+(1-t_K)\left.\frac{d\epsilon}{d\pi}\right|_{MM,dY=0}^{IEC}\right]$$

$$\left.\frac{dr}{d\pi}\right|_{MM,dY=0}^{IEC} = \frac{\frac{M}{p^2}p_\epsilon}{\psi_\epsilon} < 0$$

The nominal rate ends up lower because as ϵ falls to reestablish equilibrium, p also falls, adding somewhat to the excess supply of money which must be eliminated.

An increase in t_K

If t_K rises, at the original ϵ, the return on equities falls, and since bonds are perfect substitutes for equities, the nominal interest rate falls. At the new nominal rate there will be an excess demand for money, and again assuming that Y is fixed, in the interest elastic case there must be an increase in ϵ in order to raise the nominal rate by enough to remove the excess demand:

$$\left.\frac{d\epsilon}{dt_K}\right|_{MM,dY=0}^{IEC} = \frac{m_2(1-t_Y)(\epsilon-\delta)}{\psi_\epsilon} > 0$$

An increase in t_k shifts the MM curve up. The nominal rate ends up higher after an increase in t_k, as can be seen from the following expressions derived by differentiating (30):

$$\left.\frac{dr}{dt_K}\right|_{MM,dY=0}^{IEC} = -(\epsilon-\delta)+(1-t_K)\frac{d\epsilon}{dt_K}$$

$$= -\frac{(\epsilon-\delta)\frac{M}{p^2}p_\epsilon}{\psi_\epsilon} > 0$$

The KK Schedule

We now proceed to derive the KK schedule, the schedule which shows the

pairs of ϵ and Y that clear the market for the existing capital stock given that the conditions for profit maximization are satisfied. First we obtain expressions for the capital required in each of the industries. From (13) and (15) we have $K_1=Y_1\beta_1$ and $K_2=Y_2\beta_2$. Using (12) we have $Y_1=(Y-Y_2)/p_1$. Thus (17), which states that the market for existing capital is cleared, can be written as follows:

$$K=\left(\frac{Y-Y_2}{p_1}\right)\beta_1+Y_2\beta_2$$

Multiplying through by p_1 we obtain the condition that the total requirements of capital measured in terms of consumption goods must equal the stock of capital goods measured in terms of consumption goods:

$$p_1K=\beta_1(Y-Y_2)+p_1\beta_2Y_2$$

Using (11) and recalling that p_1, β_1, and β_2 can be written as functions of ϵ, we obtain the equation which defines the KK schedule:[17]

$$\begin{aligned}(33)\quad &\Phi(Y,\epsilon;K,g_2,T)\\ &\quad=p_1(\epsilon)K-\beta_1(\epsilon)Y\\ &\qquad-[p_1(\epsilon)\beta_2(\epsilon)-\beta_1(\epsilon)]\\ &\qquad\cdot[c(Y-T-p_1\delta K)+g_2]=0\end{aligned}$$

We view the KK schedule as giving ϵ as a function of Y and the relevant parameters of the model, which requires that $\Phi_\epsilon\neq0$.

[17] Clearly at this stage the reader is free to substitute his favorite consumption function plus g_2 for Y_2. One alternative consumption function is given in fn. 10. In general we could take Y_2 to be a function of Y and ϵ given K and a vector of other parameters. We designate this vector of other parameters α with elements α_i:

$$Y_2=Y_2(Y,\epsilon;K,\alpha)$$

The more general version of (33) is given by the following:

$$\begin{aligned}\Phi(Y,\epsilon;K,\alpha)&=p_1(\epsilon)K-\beta_1(\epsilon)Y\\ &\quad-[p_1(\epsilon)\beta_2(\epsilon)-\beta_1(\epsilon)][Y_2(Y,\epsilon;K,\alpha)]=0\end{aligned}$$

Differentiating (33), we obtain an expression from which we can determine the slope of the KK schedule and the effects of shifts in the parameters on the position of the KK schedule:[18]

$$\begin{aligned}(34)\quad d\epsilon&=\frac{(1-c_Y)\beta_1+c_Yp_1\beta_2}{\Phi_\epsilon}dY\\ &\quad-\frac{p_1+(p_1\beta_2-\beta_1)c_Yp_1\delta}{\Phi_\epsilon}dK\\ &\quad+\frac{(p_1\beta_2-\beta_1)}{\Phi_\epsilon}dg_2\\ &\quad-\frac{(p_1\beta_2-\beta_1)c_Y}{\Phi_\epsilon}dT\\ \Phi_\epsilon&=-[p_1Y_1\beta_{1\epsilon}+p_1Y_2\beta_{2\epsilon}]\\ &\quad+[K_1+(p_1\beta_2-\beta_1)c_Y\delta K]p_{1\epsilon}\end{aligned}$$

The signs of the slope of the KK schedule and of the effects of shifts in the parameters on the position of the KK schedule depend on the sign of Φ_ϵ. Because of the way we have written (33), Φ_ϵ represents the effect of a rise in ϵ on excess supply in the market for the existing stock of capital goods measured in consumption goods, *ceteris paribus*. A rise in ϵ lowers the capital-output ratios in both industries thus leading to an increase in the excess supply of capital goods; this effect, which we call the capital using effect (KUE), is given by $-[p_1Y_1\beta_{1\epsilon}+p_1Y_2\beta_{2\epsilon}]$.

The relative price p_1 may either rise or fall with an increase in ϵ depending upon the relative capital intensities of the two industries; p_1 rises ($p_{1\epsilon}>0$) if $k_1>k_2$ and falls if $k_2>k_1$. Ignoring temporarily the effects on depreciation, we can see from (33) that a rise in the relative price of capi-

[18] If we had used a more general expression for Y_2, as in fn. 17, the differential of the KK schedule would be

$$d\epsilon=-\frac{\Phi_Y}{\Phi_\epsilon}dY-\frac{\Phi_K}{\Phi_\epsilon}dK-\sum_{i=1}^{n}\frac{\Phi_{\alpha_i}}{\Phi_\epsilon}d\alpha_i$$

tal goods, p_1, raises excess supply in the market for existing capital goods. Raising p_1 increases the consumption good value of the supply of existing capital by $Kp_{1\epsilon}$. However, with Y and Y_2 fixed, the consumption good value of demand for existing capital rises by only $K_2p_{1\epsilon}$ since p_1Y_1 must remain constant. Thus excess supply in the market for existing capital rises by $K_1p_{1\epsilon}$. We call this effect the capital valuation effect (*KVE*). The argument is reversed if p_1 falls.

Excess supply also changes because of changes in the value of depreciation. This effect is represented by the term $(p_1\beta_2 - \beta_1)c_Y\delta Kp_{1\epsilon}$. The value of depreciation rises if p_1 rises when ϵ is increased. If the value of depreciation rises, then Y_2 falls, decreasing demand for capital; with a fixed Y this means that p_1Y_1 must rise, increasing the demand for capital. Whether or not there is a net increase in demand depends upon which industry has the higher capital-output ratio; that is, upon the sign of $p_1\beta_2-\beta_1$. Excess supply falls when p_1 rises if $p_1\beta_2-\beta_1<0$. It can be shown that $p_1\beta_2-\beta_1 \gtreqless 0$ as $k_2 \gtreqless k_1$.[19] This means that $p_{1\epsilon}$ and $p_1\beta_2-\beta_1$ always have opposite signs, so the effect of the change in the value of depreciation no matter what its direction is always to reduce excess supply in the market for existing capital. We call this effect the depreciation output switching effect (*DOSE*).

[19] Using Euler's theorem and the profit maximizing conditions we have

$$p_1f_1 = \frac{w}{p} + p_{1\epsilon}k_1$$

$$f_2 = \frac{w}{p} + p_{1\epsilon}k_2$$

Dividing the first equation by k_1 and the second by k_2, subtracting the second equation from the first, collecting terms, and multiplying through by $\beta_1\beta_2$ we obtain

$$(p_1\beta_2 - \beta_1) = \frac{w}{p}\frac{1}{f_1f_2}(k_2 - k_1) \gtreqless 0$$

as $k_2 \gtreqless k_1$.

When $k_1>k_2$ so that $p_{1\epsilon}>0$, Φ_ϵ is positive if the *KUE* plus the *KVE* is greater than the absolute value of the *DOSE*. When, as is often assumed, $k_2>k_1$ so that $p_{1\epsilon}<0$, Φ_ϵ is positive if the *KUE* is greater than the sum of the absolute values of the *KVE* and the *DOSE*. No matter whether $k_1>k_2$ or vice versa, Φ_ϵ is more likely to be positive the more alike are the two sectors, for as $k_1 \to k_2$, we have $p_{1\epsilon} \to 0$, $p_1\beta_2 \to \beta_1$, so the *KVE* and the *DOSE* tend to disappear. Since we believe that the case in which Φ_ϵ is positive is the more important case, we concern ourselves primarily with that case. Since the always positive part of Φ_ϵ depends on substitution in production, we call the case when Φ_ϵ is positive the strong substitution case (*SSC*) and the case when Φ_ϵ is negative the weak substitution case (*WSC*).

Given the sign of Φ_ϵ we can readily find the signs of the slope of the *KK* curve and of the effects on the position of the *KK* curve of changes in the parameters. As Y is increased both Y_2 and p_1Y_1 must rise. These increases generate an increase in the demand for capital. In the strong substitution case, ϵ must rise in order to choke off this excess demand and reestablish equilibrium in the market for existing capital goods. This case is shown in Figure 1.

From (34) we have:

$$\left.\frac{d\epsilon}{dY}\right|_{KK}^{SSC} = \frac{(1 - c_Y)\beta_1 + c_Yp_1\beta_2}{\Phi_\epsilon} > 0$$

Of course, in the weak substitution case the *KK* curve slopes downward.

Reference to (34) makes it easy to determine the effects on the *KK* schedule of changes in the parameters K, g_2, and T.

An increase in the capital stock

At a given level of *GNP*, the effect of an increase in K on the ϵ that clears the market for existing capital and guarantees that

profits are maximized is given by

$$\left.\frac{d\epsilon}{dK}\right|^{SSC}_{KK,dY=0} = -\frac{[p_1+(p_1\beta_2-\beta_1)c_Y p_1\delta]}{\Phi_\epsilon} < 0$$

We are assuming that the numerator of the above derivative is positive, which will be true if δ is sufficiently small or if k_1 is not very much greater than k_2. An increase in K increases the excess supply of capital at a given Y, which means that, in the strong substitution case, ϵ (and therefore p_1p and p) must fall if the market for existing capital is to be cleared. An increase in K thus shifts the KK curve downward.

An increase in government purchases of consumer goods

At a given level of GNP, the effect of an increase in g_2 on the ϵ that clears the market for existing capital and guarantees that profits are maximized is given by

$$\left.\frac{d\epsilon}{dg_2}\right|^{SSC}_{KK,dY=0} = \frac{(p_1\beta_2-\beta_1)}{\Phi_\epsilon} \gtrless 0 \quad \text{as} \quad k_2 \gtrless k_1$$

At a given level of Y, and at the ϵ on the original KK schedule, the output of the consumption-goods sector must expand by dg_2, requiring the output of investment goods to contract by dg_2. At the original levels of p_1, p, and ϵ, firms in the consumption goods sector require $p_1\beta_2dg_2$ additional units of capital to produce the additional output, while capital-producing firms willingly release β_1dg_2 units of capital in order to lower their output by dg_2. If $p_1\beta_2dg_2$ equals β_1dg_2, the market for existing capital remains cleared at the old p_1, p, and ϵ. If $k_2>k_1$, implying that $p_1\beta_2>\beta_1$, the consumption sector demands more additional capital at the original levels of p, ϵ, and p_1p than the capital-producing firms are willing to sell or rent. Thus, there is an excess demand for existing capital, and ϵ (and also p_1p and p) must rise to clear the market for existing capital, given Y. This implies that an increase in g_2 shifts the KK curve upward if $k_2>k_1$. If $k_2<k_1$, the KK curve shifts downward when g_2 increases, while, as we have seen, the KK curve remains unchanged when $k_1=k_2$.

An increase in total real tax collections

The effect of a change in T on the value of ϵ that, given Y, lies on the KK schedule is given by

$$\left.\frac{d\epsilon}{dT}\right|^{SSC}_{KK,dY=0} = \frac{-(p_1\beta_2-\beta_1)c_Y}{\Phi_\epsilon} \gtrless 0 \quad \text{as} \quad k_1 \gtrless k_2$$

An increase of dT has the same effect on the KK schedule as a decrease in government expenditures of (dT/c_Y). The increase in T causes the demand for consumption goods to fall, thereby causing the capital-market-clearing value of ϵ to fall, stay the same, or rise depending on whether k_2 exceeds, equals, or falls short of k_1.

Full Equilibrium

We are now in a position to describe the momentary equilibrium of our economy and the manner in which it responds to the imposition of disturbances. Equilibrium values of ϵ and Y are determined at the intersection of the MM and KK curves, as in Figure 1. Where both the KK and the MM curves are upward sloping, as we have been assuming for the most part, the MM curve must be steeper than the KK curve if the equilibrium is to be stable, a condition that we will assume to be satisfied.[20]

We now describe the effects on momentary equilibrium of changes in the parameters M, w, π, t_Y, t_K, g_2, and T. These effects are summarized in Table 1.

[20] Stability also requires that, in a certain sense, price adjustments in the market for paper assets are swift relative to price adjustments in the market for existing physical capital. A formal discussion of stability is contained in the Appendix.

TABLE 1—SUMMARY OF RESULTS[a]

Effect on	Increase in M	w	t_Y	t_K	π	g_2: $k_2>k_1$ IEC	g_2: $k_2>k_1$ IIC	g_2: $k_1>k_2$ IEC	g_2: $k_1>k_2$ IIC
Y	+	−	−	−	+	+	−	−	+
N	+	−	−	−	+	?	?	?	?
p	+	−	−	−	+	+	+	−	−
pp_1	+	−	−	−	+	+	+	−	−
ϵ	+	−	−	−	+	+	+	−	−
r	+	−	−	−	+	+	+	−	−

[a] The results reported in this table are based on the assumption that the KK schedule has a positive slope and on the assumption in fn. 22 about the effect of a rise in ϵ on employment. The results reported in columns headed by IEC are based on the assumption that the MM schedule has a positive slope. The results reported in columns headed by IIC are based on the assumption that the MM schedule has a negative slope. The results for an increase in T with t_Y and t_K constant are just the reverse of those for an increase in g_2.

An increase in the money supply

An increase in the money supply shifts the MM curve downward, indicating that ϵ must fall if portfolio balance is to be maintained at the original level of GNP, say Y_0 in Figure 1. To equilibrate the money market, r and ϵ tend to fall. Perceiving that wealth-holders are willing to accept a lower rate of return on equities, firms now find it profitable to use more capital intensive techniques and bid for capital goods. This causes the money price of capital goods, p_1p, to rise. Since the money wage rate is unchanged and since firms must continue just to cover costs, p must rise when p_1p rises.[21] The rise in p both reduces the supply of real balances and raises the level of output that profit-maximizing firms want to produce with the existing capital stock. These two effects tend to create excess demand for real balances, which means that r and ϵ must rise. The rise in p also increases the real rate of return to capital implied by profit maximization. Our assumption that the MM schedule is steeper than the KK schedule guarantees that as output and prices rise, the portfolio-balancing ϵ eventually "catches up" with the capital-market-clearing ϵ, establishing a new equilibrium at higher values of both ϵ and Y, as in Figure 1. The rise in ϵ is necessitated by the higher marginal product of capital that prevails at the new equilibrium. The increase in the money supply also produces rises in N, r, p, and pp_1.[22] Whether or not

21
$$\frac{d\{p_1[\epsilon(p,w)]p\}}{dp} = p\frac{dp_1}{dp} + p_1$$

where $\epsilon(p, w)$ is obtained by "inverting" (27). Thus

$$\frac{dp_1(p)p}{dp} = \frac{w}{pk_2f_1}[k_1 - k_2] + p_1$$
$$= \frac{w}{pk_2f_1}k_1 + \frac{k_2(pp_1f_1 - w)}{pk_2f_1} > 0$$

That is, through equation (20) a rise in p_1p causes a fall in k_1 which through equation (19) leads to a rise in ϵ. This in turn requires a fall in k_2 through equation (21), which necessitates a fall in the real wage in terms of the consumption good. Thus p must rise.

22 The effects on employment produced by changes in the parameters can be seen by analyzing the following expression for labor employed, N:

$$N = \lambda_1(\epsilon)\left\{\frac{Y - c[Y - T - p_1(\epsilon)\delta K] - g_2}{p_1(\epsilon)}\right\} + \lambda_2(\epsilon)\{c[Y - T - p_1(\epsilon)\delta K] + g_2\}$$

where $\lambda_1 = 1/f_1$, $\lambda_2 = 1/f_2$ and $\lambda_{1\epsilon}, \lambda_{2\epsilon} > 0$

Upon differentiation we have:

p_1 rises or falls depends on relative capital intensities.

An increase in the money wage

An increase in the money wage acts exactly like a decrease in the money supply. The increase in w causes the MM curve to shift up, since for profit-maximization, p must rise, creating excess demand for money at the original Y and ϵ, tending to drive ϵ upward. The tendency for ϵ to rise causes firms to attempt to rent or sell capital, causing p_1p, p, ϵ, and output to fall. Equilibrium is reestablished at values of ϵ and Y lower than those characterizing the original equilibrium.

An increase in anticipated inflation

An increase in the expected rate of inflation π shifts the MM curve downward, eventually resulting in increases in both ϵ and Y. At the original level of GNP, the increase in π reduces the ϵ required for portfolio balance. This causes firms to bid for capital, causing p_1p, p, ϵ and Y to increase.

An increase in the income tax rate with total real tax collections held constant

An increase in t_Y reduces the attractiveness of bonds and equities, creating an excess demand for money at the original ϵ and Y. At the original Y, r and ϵ must rise in order to equilibrate the money market; that is, the MM schedule shifts upward. The rise in ϵ causes firms to attempt to rent or sell capital, causing p_1p, p, ϵ, and Y to fall until equilibrium is reestablished at values of ϵ and Y that are lower than those characterizing the original equilibrium.

An increase in the profit tax rate with total real tax collections held constant

An increase in t_K causes the MM schedule to shift upward, thereby depressing ϵ and Y. The rise in t_K means that at the initial Y the original ϵ now implies a lower rate of return to equities, causing wealth-holders to attempt to move into money. This creates a tendency for r and ϵ to rise at the original Y, causing firms to attempt to dispose of capital, driving p_1p, p, ϵ, and Y downward.

An increase in government purchases of consumer goods

The effects of an increase in g_2 depend on the relative capital intensities of the two sectors. If $k_2 > k_1$, the increase in g_2 increases the capital-market-clearing value of ϵ. This occurs because at the original Y

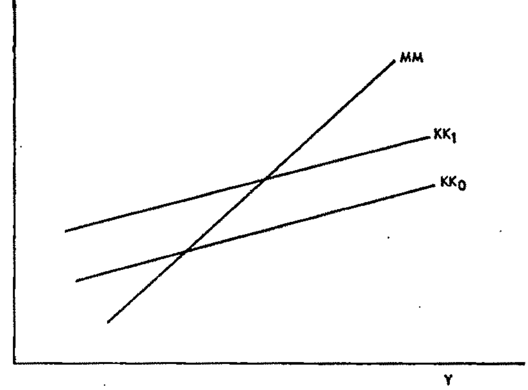

FIGURE 2

$$dN = \left\{ Y_1\lambda_{1\epsilon} + Y_2\lambda_{2\epsilon} - \frac{1}{p_1}\left[N_1 + (p_1\lambda_2 - \lambda_1)c_Y\delta K\right]p_{1\epsilon} \right\} d\epsilon + \frac{1}{p_1}\left[(1-c_Y)\lambda_1 + c_Y p_1\lambda_2\right]dY + \frac{1}{p_1}(p_1\lambda_2 - \lambda_1)dg_2 - \frac{1}{p_1}(p_1\lambda_2 - \lambda_1)c_Y dT - \frac{1}{p_1}(p_1\lambda_2 - \lambda_1)c_Y p_1\delta dK$$

Raising ϵ with Y constant increases the labor-output ratio in both industries which tends to increase employment. An increase in ϵ also gives rise to two effects analogous to the KVE and the $DOSE$ effects pertinent for evaluating Φ_ϵ above. These two effects may tend to decrease employment as ϵ is increased. However, these effects become smaller as $k_1 \to k_2$, and we assume that k_1 and k_2 are close enough together that a rise in ϵ increases employment. A rise in output with ϵ constant always increases employment. Since ϵ and Y always move together when changes occur in M, w, t_Y, t_K, and π, N always moves in an unambiguous direction given our assumptions.

and ϵ the rise in g_2 increases the amount of capital demanded by the consumption goods sector by more than the capital producing firm can release and still have Y remain constant. This causes firms to bid for capital, causing p_1p, p, ϵ, and Y to increase. On the other hand, if $k_1>k_2$, an increase in g_2 shifts the KK schedule downward, causing Y and ϵ to fall. In both cases the effect on employment is ambiguous.[23] If $k_1=k_2$, an increase in g_2 has no effects on Y, N, p, ϵ, or p_1. Of course, N_1, N_2, K_1, and K_2 will change according to

$$dK_2 = \beta_2 dg_2$$

$$dK_1 = -\frac{\beta_1}{p_1}dg_2 = -dK_2$$

$$dN_2 = \frac{\beta_2}{k_2}dg_2$$

$$dN_1 = -\frac{\beta_1}{k_1p_1}dg_2 = -dN_2$$

In this case, market forces induce producers of capital goods to release just the amounts of capital and labor that producers of consumer goods need to meet the increased demand for their output. At the initial equilibrium values of Y, Y_1, and Y_2, the increased demand for consumer goods caused by the increase in g_2 produces a tendency for p to rise, while p_1p remains constant. The rise in p induces a rise in profits of consumer goods producers, while profits of investment goods producers remain unchanged:

$$\left.\frac{d\sum_1}{dp}\right|_{dp_1p=0} = 0$$

$$\left.\frac{d\sum_2}{dp}\right|_{dp_1p=0} = (1-t_K)Y_2 > 0$$

The rate of return on capital in the consumer goods industry rises, exceeding that in the investment goods industry. This causes firms in the consumer goods industry to bid for capital, which firms in the investment goods industry are willing to sell or rent to them in order to obtain the highest possible rate of return on their capital. The slightest upward pressure on p is thus sufficient to bring about any required changes in the distribution of capital and employment. Consequently in equilibrium, p and p_1 remain at their initial levels, as do Y and N.[24]

An increase in total real tax collections, tax rates being held constant

An increase in T with t_y and t_K held constant operates in the same fashion as a

[23] The expression in fn. 22 reveals the source of this ambiguity. When g_2 is increased, ϵ and Y move in the same direction if the MM curve slopes upward. When $k_2>k_1$, ϵ and Y both rise. However, an increase in g_2 also has an employment-reducing effect in addition to the employment-increasing effects of the increases in ϵ and Y. At a constant Y, a rise in g_2 shifts production from the good with the higher labor-output ratio, Y_1, to the good with the lower labor-output ratio, Y_2, thus reducing employment. A similar argument reveals an ambiguity in the effect of a rise in g_2 on employment when $k_1>k_2$.

[24] Notice that we are assured that, at the initial equilibrium values of p_1, p, r, and Y, the government is able to finance the increase in the deficit caused by the increase in g_2. Substituting the national income identity and the government budget constraint into the definition of disposable income, and noting that saving plus consumption equals disposable income, we arrive at

$$S = p_1DK + \frac{DM}{p} + \frac{DB}{p}$$

where S is saving and p_1DK equals the real value of the rate at which firms are issuing equities to finance their capital accumulation. The above equation states that in equilibrium the rate at which households are actually acquiring equities, bonds, and money must equal the rate at which they desire to save. Where capital intensities are equal, the increase in g_2 produces an equal reduction in p_1DK and hence in the rate at which firms issue equities. This is precisely enough of a decrease to offset the increase in the rate at which the government must issue bonds and/or money, since $dg_2=-p\,dDK$, and since from the government budget constraint and the fact that prices don't jump,

$$dg_2 = d\left(\frac{DM}{p}+\frac{DB}{p}\right)$$

decrease in g_2. With an upward sloping MM curve, an increase in T drives Y and ϵ up (down) when $k_1>k_2(k_2>k_1)$.

The "Interest Inelastic Case"

The analysis above assumes that the interest elasticity of the demand for money is sufficiently high in absolute value to make the MM curve upward sloping. We now briefly consider the interest inelastic case, in which the MM curve slopes downward. We continue to assume that the KK schedule slopes upward.

Reference to equation (32), which gives the differential of the MM schedule, establishes that when the MM schedule is downward sloping, the MM schedule is shifted *upward* by *increases* in the money supply and the anticipated rate of inflation, and by *decreases* in w, t_K, and t_y. It follows that in the interest inelastic case, changes in M, w, π, t_K, and t_y exert effects on Y, ϵ, p, and p_1p that are qualitatively the same as those in the interest elastic case in which the MM schedule is upward sloping.

Where the possibility of a downward sloping MM curve does create some ambiguity is in the analysis of changes in g_2 and T. Suppose that $k_2>k_1$ and that the government increases its purchase of consumer goods, causing KK to shift upward, as in Figure 3. At the original Y, the capital-market-clearing value of ϵ rises, causing firms to bid for capital, raising p_1p and p. The rise in p diminishes the supply of real balances tending to create excess demand for real balances. Since the interest elasticity of the demand for money is relatively small, large increases in r, and therefore in the ϵ required by wealthholders, are required in order to diminish the demand for real balances by a given amount. The ϵ consistent with portfolio balance tends to rise above the value of ϵ that with the new KK schedule clears the capital market at the old level of output. This causes firms to attempt to dispose of

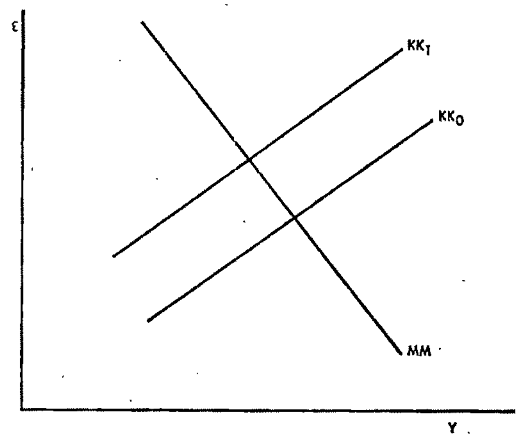

FIGURE 3

capital exerting downward pressure on p_1p, p, ϵ, and output. Output and ϵ fall until eventually equilibrium is restored at a lower Y but at a higher ϵ than characterized the initial equilibrium.

The upshot is that in the interest inelastic case, an increase in g_2 decreases the level of output if $k_2>k_1$. Similarly, an increase in g_2 increases (leaves unchanged) output if $k_1>k_2$ $(k_1=k_2)$. Once again the effect on employment is ambiguous no matter which good is more capital intensive.[25]

III. Conclusions

Increases in the money supply and the expected rate of inflation and decreases in the money wage and the marginal income and profits tax rates increase output, employment, and prices in our model. Those changes have their effects by introducing disturbances in the markets for stocks of physical and paper assets, thereby exerting

[25] The expression in fn. 22 reveals the source of this ambiguity When g_2 is increased, ϵ and Y move in opposite directions if the MM curve slopes downward. When $k_2>k_1$, ϵ rises, and Y falls. The rise in ϵ tends to increase employment; the fall in Y tends to reduce it. As mentioned in fn. 23 there is an additional employment reducing effect caused by a shift in output between sectors. A similar argument reveals an ambiguity in the effect of a rise in g_2 on employment when $k_1>k_2$.

pressure on prices, causing firms to adjust their levels of output and employment. On the other hand, increases in the level of government expenditures and decreases in tax collections may either increase or decrease output and employment depending upon the relative capital intensities of the two production sectors and some other conditions involving the interest elasticity of the demand for money. These fiscal policies affect output and employment only to the extent that consumption goods and capital goods are not perfect substitutes in production; if they are perfect substitutes, the rates of government expenditures and of tax collections play no role in the determination of output and employment at a point in time.

These properties of our model serve to highlight just how important are the characteristics of the market in existing physical capital. The assumption made here is that a "perfect" market exists, one in which firms can buy and sell capital with zero transactions costs. This implies that profit-maximizing firms will hold the optimal quantity of capital at each instant. Firms' trading in the market for existing capital will thus guarantee that the profit-maximizing marginal conditions for capital are met at each instant, just as the marginal conditions for labor are assumed to be met in the standard Keynesian model. This makes the market for existing capital a critical element in the mechanism by which policy changes and other disturbances affect the economy.

On the other hand, the Keynesian model denies the presence of a market in existing capital and permits discrepancies to exist at any moment between the marginal product of capital and the cost of capital. High transactions costs are assumed to prevent firms from adjusting their capital stocks instantaneously. Instead, they are assumed to respond to an increase in the gap between the marginal product of capital and the cost of capital, as might be caused by a decline in the interest rate, by increasing the rate at which they are investing. Thus, the Keynesian model posits investment demand curves for firms rather than insisting that the marginal conditions for capital always be satisfied, as we have done here. That feature of the Keynesian model is an extremely important one in making variations in government expenditures a potent instrument for stabilization with predictable effects on output and employment in the short run.

Appendix

Equations (11) to (23) can also be reduced to a system of two equations in p and ϵ. The implicit relationship between ϵ, p, and w used to derive (27) can also be used to write the following:

$$(A1) \quad \hat{\epsilon} = \hat{\epsilon}(p; w) \quad \text{where} \quad \hat{\epsilon}_p = \frac{1}{p_\epsilon} > 0$$

$$\hat{\epsilon}_w = p_w \frac{wf_2}{p^2 p_1^2 f_1} < 0$$

$\hat{\epsilon}$ is the rate of return on capital in terms of capital goods implied by profit maximization at a given p. We now use ϵ to denote the rate of return on capital which is necessary for portfolio balance. Equilibrium requires that the rate of return on capital implied by profit maximization must equal the rate of return on capital required for portfolio balance:

$$(A2) \quad \Gamma(\epsilon, p; w) = \hat{\epsilon}(p; w) - \epsilon = 0$$

Using (A1) we can rewrite (33) in the following way:

$$\begin{aligned} \theta(Y, p; w, K, g_2, T) &= p_1(\hat{\epsilon})K - \beta_1(\hat{\epsilon})Y \\ &\quad - [p_1(\hat{\epsilon})\beta_2(\hat{\epsilon}) - \beta_1(\hat{\epsilon})] \\ &\quad \cdot \{c[Y - T - p_1(\hat{\epsilon})\delta K] + g_2\} = 0 \end{aligned}$$

Since $\theta_Y \neq 0$, we can use this implicit relationship between Y and p to solve for Y in terms of p and the relevant parameters:

$$(A3) \quad Y = Y(p; w, K, g_2, T)$$

where

$$Y_p = -\frac{\theta_p}{\theta_Y} = -\frac{\Phi_\epsilon \frac{1}{p_\epsilon}}{\Phi_Y} = \left\{\frac{1}{\left.\frac{d\epsilon}{dY}\right|_{KK}}\right\}\frac{1}{p_\epsilon}$$

Y_p has the same sign as the slope of the KK curve, so, given the assumptions in the text, Y_p is positive. Substituting (A3) into (18) and using (23) we arrive at the following:

$$\text{(A4)}\quad \Omega(\epsilon, p; w, K, g_2, T, M, t_Y, t_K, \pi) = m\{Y(p; w, K, g_2, T), (1-t_Y)\cdot[(1-t_K)(\epsilon-\delta)+\pi]\} - \frac{M}{p} = 0$$

The description of the pressures toward adjustment given in the text can be written down explicitly in the following pair of differential equations (A5) and (A6).

Employing the usual technique, we linearize the system around the equilibrium values for ϵ and p which we call ϵ_0 and p_0. See equation (A7) below. All the derivatives are evaluated at (ϵ_0, p_0). The characteristic equation of the system is

$$\text{(A8)}\quad \lambda^2 + B\lambda + C = 0$$

$$B = \left\{\mu_1\left[\frac{r}{(1-t_Y)(1-t_K)}\right]\cdot\left[\frac{m_2(1-t_K)(1-t_Y)}{M/P}\right] + \mu_2\left[\frac{pp_1}{p_1+pp_{1\epsilon}/p_\epsilon}\right]\left[\frac{1}{\epsilon p_\epsilon}\right]\right\}$$

$$C = \mu_1\mu_2\left[\frac{r}{(1-t_Y)(1-t_K)}\right]\cdot\left[\frac{pp_1}{p_1+pp_{1\epsilon}/p_\epsilon}\right]\left[\frac{p}{M\epsilon p_\epsilon}\right]$$

$$\text{(A5)}\quad \frac{Dr(\epsilon)}{r(\epsilon)} = \mu_1\left[\frac{m\{Y(p; w, K, g_2, T), (1-t_Y)[(1-t_K)(\epsilon-\delta)+\pi]\} - \frac{M}{p}}{\frac{M}{p}}\right]$$

$$\text{(A6)}\quad \frac{D(pp_1[\hat{\epsilon}(p; w)])}{pp_1[\hat{\epsilon}(p; w)]} = \mu_2\left\{\frac{\hat{\epsilon}(p)-\epsilon}{\hat{\epsilon}(p)}\right\}$$

$$\text{(A7)}\quad \begin{bmatrix} \frac{(1-t_Y)(1-t_K)}{r}(D\epsilon - D\epsilon_0) \\ \\ \frac{p_1+pp_{1\epsilon}\frac{1}{p_\epsilon}}{pp_1}(Dp-Dp_0) \end{bmatrix} = \begin{bmatrix} \mu_1\frac{m_2(1-t_K)(1-t_Y)}{\frac{M}{p}} & \mu_1\left\{\frac{\frac{M}{p^2}+m_1Y_p}{\frac{M}{p}}\right\} \\ \\ \mu_2\left(-\frac{1}{\epsilon}\right) & \mu_2\left\{\frac{\frac{1}{p_\epsilon}}{\epsilon}\right\} \end{bmatrix}\begin{bmatrix} \epsilon-\epsilon_0 \\ \\ p-p_0 \end{bmatrix}$$

$$\cdot\left[m_2(1-t_K)(1-t_Y)+\frac{M}{p^2} + m_1\frac{1}{\left.\frac{d\epsilon}{dY}\right|_{KK}}\right]$$

Necessary and sufficient conditions for stability are $B>0$ and $C>0$. Our assumption that markets adjust instantaneously implies that $\mu_1, \mu_2 \to \infty$. For stability we must have μ_1 and μ_2 approach infinity in such a way that B remains positive. The following condition must always hold:

$$\frac{\mu_2}{\mu_1} < \frac{\frac{p}{M} r \,|\, m_2 \,|}{\left[\frac{pp_1}{\epsilon(p_1 p_\epsilon + p p_{1\epsilon})}\right]}$$

The ratio of the speed of adjustment in the market for existing capital to the speed of adjustment in the money market must be less than the ratio of the effect of a rise in ϵ on the percent excess demand for money to the effect of a rise in p on the percent gap between the profit-maximizing and the portfolio-balancing rate of return on capital. Adjustment must be relatively more rapid in the markets for paper assets. This condition is necessary because a rise in p raises $\hat{\epsilon}$, thus increasing the gap between the profit-maximizing and portfolio-balancing rates of return. If μ_2 is small enough, where "small enough" is defined by the condition above, to keep this disequilibrating effect from becoming dominant, then the system as a whole is stable.

For C to be positive the following condition must hold:

$$m_2(1-t_K)(1-t_Y)+\frac{M}{p^2}\,p_\epsilon+m_1\left(\frac{1}{\left.\frac{d\epsilon}{dK}\right|_{KK}}\right)>0$$

This condition can be rewritten as the following:

$$-\frac{1}{\left.\frac{d\epsilon}{dY}\right|_{MM}}+\frac{1}{\left.\frac{d\epsilon}{dK}\right|_{KK}}>0$$

With our assumptions that

$$\left.\frac{d\epsilon}{dK}\right|_{KK}>0$$

stability is assured if

$$\left.\frac{d\epsilon}{dY}\right|_{MM}<0$$

If

$$\left.\frac{d\epsilon}{dY}\right|_{MM}>0$$

then we must have

$$\left.\frac{d\epsilon}{dY}\right|_{MM}>\left.\frac{d\epsilon}{dY}\right|_{KK}$$

for stability.

The Demand for State and Local Government Employees

By RONALD G. EHRENBERG*

During the 1953–70 period, state and local government employment grew faster than total employment, rising from 8.6 percent to 14.0 percent of total employment on payrolls of nonagricultural establishments. While much of the rise was due to the growth of educational employment (145 percent), state and local noneducational employment also grew significantly faster (79 percent) than employment in the private nonagricultural economy (33 percent). Indeed, several noneducational employment categories have grown at rates approaching or exceeding that of educational employment in recent years (Table 1). By 1980, state and local government employment is projected by the Bureau of Labor Statistics to increase further to 15.9 percent of total nonagricultural payroll employment.[1]

Interest in the determinants of the level of such employment within a state and its allocation across functional categories is more than academic. Recently, fears have been expressed that the growing strength of public employee unions, their increased militancy, and the trend toward collective bargaining rights with respect to wage issues, will lead to inflationary wage increases in the sector and aggravate the financial problems facing state and local governments.[2] These fears are explicitly based upon the assumption that public services are essential and consequently that the demand for public employees is wage inelastic. To many, the logical conclusion then drawn is that limitations should be placed on the collective bargaining rights of these groups.[3]

To date, however, no estimates have been presented of the *wage elasticities* of demand for public employees and consequently no quantitative discussion of the strength of the market forces, which might prevent such increases, has occurred. To the extent that state and local government employee unions value both the wage and employment levels of their members, high wage elasticities coupled with projected relatively slower rates of growth of employment demand would help to moderate the size of wage increases which they will seek in the future.

One can easily think of possibilities for substituting capital for labor in the provision of public services (for example, police patrol cars) and for substituting private for public provision (for example, private security agencies). Moreover, given the limited resources which state and local

* Associate professor of economics, University of Massachusetts. Without implicating them for what remains, I am grateful to Orley Ashenfelter, James Kindahl, a referee, and the editor for their comments on earlier versions of the paper. The research was supported by a faculty research grant from the Manpower Administration, U.S. Department of Labor and the material presented here draws from my larger study (1972), prepared for that organization.

[2] Harry Cohany and Lucretia Dewey, Sheila White' and Sheila Weissbror present descriptions of these trends. Table 1 presents data which indicate that both over the 1961–70 and 1965–70 periods, state and local government employees' wages have increased more rapidly than wages in the private sector. However, as suggested by the editor, the past relative inflation of public employees' wages was probably due to the rapid growth of employment demand in the sector and unrelated to the wage elasticities of demand.

[3] See, for example, Harry Wellington and Ralph Winter.

TABLE 1—TOTAL PERCENTAGE CHANGES FULL-TIME EQUIVALENT STATE AND LOCAL GOVERNMENT EMPLOYMENT AND MONTHLY PAYROLL PER MAN, BY FUNCTION

	Employment		Payroll Per Man

governments can command, an increase in the relative price of a public service should lead to a substitution against that service. Thus, it is not obvious, a priori, that the wage elasticities of demand for all categories of state and local government employees are inelastic.

The primary purpose of this paper is to present empirical estimates of the wage elasticities of demand for different categories of state and local government employees. The employment demand equations that are estimated are derived from a utility maximization model of state and local government behavior. After presenting this model in the first section, we next briefly discuss the data used in the study. The structural system of demand equations is then estimated using pooled time-series and cross-section information, with annual individual state data as the units of observation. A number of alternative estimation methods are used in the analysis. Parameter estimates obtained from the model are utilized in the final section to simulate the *disemployment effects* of postulated future relative wage increases for individual classes of state and local government employees, as well as increases for all classes relative to the private sector.

Our estimates indicate that statistically significant negative wage elasticities of demand exist for almost all functional categories of state and local government employees. However, these elasticities do appear to be inelastic and consequently the simulated disemployment effects are quite small. Thus, while there is evidence that state and local government decision makers respond to market forces in choosing their employment portfolios, these responses do not appear to be sufficiently

strong to limit the size of real wage increases which state and local government employees may seek in the future.

I. Theoretical Structure

Abstracting from the myriad of state and local government bodies within a state, we consider a single decision-making unit which is assumed to determine the allocation of state resources between public and private production and also the per capita level and functional distribution of state and local government employment. Employing a "utility-tree" approach, let the utility function of this unit be written as

$$(1)\quad U = U\left[V^A\begin{bmatrix}\text{privately}\\ \text{produced}\\ \text{goods and}\\ \text{services}\end{bmatrix}, V^B\begin{bmatrix}\text{publicly}\\ \text{produced}\\ \text{goods and}\\ \text{services}\end{bmatrix}\right]$$

The decision-making body is assumed to derive utility from the various categories of public services, with the per capita service flow from each category being proportional to the per capita category employment level. At each point in time, for any function, the factor of proportion is assumed constant across states. Hence, we are implicitly assuming no quality differentials within an employment category across states and, since state price indices for the "cost of capital" do not exist, we have also ignored the possibility of substituting capital for labor.

Specifically, suppose that the branch utility function (V^B) is of the form,[4]

$$(2)\quad V^B = V^B\left[\frac{M_1}{P} - \frac{b_1}{P}, \frac{M_2}{P} - \frac{b_2}{P}, \ldots, \frac{M_n}{P} - \frac{b_n}{P}\right]$$

$$M_j > b_j \text{ for all } j$$

Here, M_k is the full-time equivalent state and local government employment level of the kth functional category, b_k is the minimum required number of type k employees, P is the state population, and there are n functional employment categories.

The minimum required employment levels are introduced because state and local government decision making is often alleged to be conducted on an incremental basis, with previous departmental budgets or employment levels taken as given.[5] To allow for this possibility we assume, in a manner analogous to that of Pollack and Wales, that the minimum required number of employees in a category is proportional to the lagged category employment level.

$$(3)\quad b_k = \alpha_k M_k^{t-1}, \quad 0 \leq \alpha_k \leq 1, \quad k = 1, 2, \ldots, n$$

Employment decisions are strictly incremental if the α_k are all unity, while the entire employment portfolio is a decision variable if all the α_k are zero. Intermediate values indicate that the category employment levels can be cut to some extent. An interpretation of (2) and (3) is then as follows: For any level of budgeted funds, the decision-making body first makes expenditures for the minimum required numbers of employees and then with the remaining budgeted funds, chooses the increments to these employment levels so as to maximize

[4] A specific member of this class of utility functions is the Stone-Geary utility function,

$$U(M) = \sum_{k=1}^{n} a_k \log\left(\frac{M_k}{P} - \frac{b_k}{P}\right), \quad a_k > 0, \quad \sum_{k=1}^{n} a_k = 1$$

Richard Stone, Richard Parks, and Robert Pollack and Terrance Wales utilize this utility function to derive and estimate consumer demand functions.

[5] Ira Sharkansky and the references cited therein present evidence that agencies are seldom cut below their previous levels of appropriations. However this in itself is not evidence of incremental budgeting, for with growing state and local government budgets it is conceivable that the appropriate marginal conditions would dictate that all agencies be expanded anyway.

the branch utility function (V^B) which depends only on the per capita increments.

Suppose that the decision makers seek to maximize the "higher-level" utility function (1) subject to a constraint that involves total available resources in the state, here assumed to be a function of per capita personal income and per capita grants from the federal government, and the prices of the various individual publicly and privately produced services. If we further assume that the higher-level utility function is strongly separable, which requires that the marginal rates of substitution between different categories of public services be independent of "consumption" levels of privately produced services, then Robert Strotz has shown that the decision makers will optimally follow a two-stage process.[6] First the expenditure levels for each aggregated branch (public vs. private) will be selected with the resources allocated to each branch being a function only of the total resources available and the aggregate branch price indices. Then expenditure levels for specific commodities, in either the public or private branch, will be determined as functions of the total own branch expenditure level and the specific prices of all commodities within the branch alone.

If we assume that the per capita total state and local government employment budget in a state is approximately proportional to the per capita "public branch allocation," the above suggests that it is reasonable to specify the per capita total employment budget (B/P) as being determined by,[7]

$$\log(B/P) = S_0 + S_1 \log(RW) + S_2 \log(G/P) + S_3 \log(Y/P) \tag{4}$$

Here Y/P is per capita personal income, G/P is per capita grants from the federal government to state and local governments in the state and RW is a measure of the average relative cost of publicly produced to privately produced goods and services. For empirical purposes RW is defined as the ratio of average monthly earnings of state and local government employees to the comparable figure for manufacturing production workers in the state.

Once the per capita total employment budget is determined, the decision makers choose the per capita level and functional distribution of state and local government employment by maximizing the branch utility function (2) subject to (3) and the constraint that the total employment budget be exhausted.

$$\sum_{k=1}^{n} W_k(M_k - b_k) = B - \sum_{k=1}^{n} W_k b_k \tag{5}$$

W_k is the monthly payroll cost per employee of the kth category. Assuming that the customary regularity conditions hold for (2), its maximization subject to (3) and (5) yields a general system of category employment demand equations.

$$\frac{M_j^t}{P} - \frac{\alpha_j M_j^{t-1}}{P} = F\left(W_1, W_2, \ldots, W_n, \left(B - \sum_{k=1}^{n} W_k \alpha_k M_k^{t-1}\right) \Big/ P\right) \quad j = 1, 2, \ldots, n \tag{6}$$

In our empirical work (6) is approxi-

[6] As we have already indicated in our introduction, the strong separability assumption is not strictly valid as many services produced in the public sector have viable private substitutes. Furthermore, privately produced but publicly purchased services would be included in branch A. Nevertheless, the assumption is useful in that it provides an analytic foundation for (4).

[7] Decision makers are viewed in (4) as having sufficient flexibility so that even grants tied to specific functions serve to increase the total employment budget, rather than only the specific category budget. Moreover, matching grants are assumed to have only income and not price effects. A long literature exists (for example, Edward Gramlich and David Smyth) which neither conclusively support nor refute these assumptions. Federal grants are also treated as being exogenous for our purposes. Our formulation is dictated by data considerations and the particular functional form is chosen for analytic convenience.

mated by the following system of log-linear employment demand equations.[8]

$$(7)\quad log\left(\frac{M_j^t}{P}-\frac{\alpha_j M_j^{t-1}}{P}\right)=b_{0j}+b_{1j}\,log\,W_j$$
$$+b_{2j}\,log\left(B-\sum_{k=1}^{n}W_k\alpha_k M_k^{t-1}\right)\Big/ P$$
$$+\sum_{R=1}^{m}c_{Rj}\,log\,SDR \qquad j=1,2,\ldots,n$$

To avoid problems of severe multicollinearity, (7) excludes all wage variables except the employment category's own wage. Furthermore, since it is erroneous to specify that the relative importance of the various services are constant across states or within a state over time, the system includes as explanatory variables those sociodemographic variables (*SDR*) that are expected to influence the decision makers' tastes for the various services.[9] On the basis of data availability and preliminary experimentation, the variables utilized are the state population density (*SD*1), the proportion of the state population ages 5–17 (*SD*2), and the proportion of the state population over age 65 (*SD*3). The system of $n+1$ equations contained in (4) and (7) is estimated in Section III.[10]

[8] The specific utility function found in fn. 4 leads directly to the system of demand equations in (7), with the further restrictions that $b_{1j}=-1$ and $b_{2j}=1$ for all j. Since we are primarily interested in ascertaining the magnitude of the wage and employment budget elasticities of demand, these restrictions are not imposed in the estimation and the specific functional form of the utility function is not assumed a priori. However, we emphasize that (7) must then be regarded only as an approximation to a true system of demand equations.

Note that if government employers face positively sloped labor supply curves, the wage elasticities estimated from (7) will be biased in a positive direction. Orley Ashenfelter presents evidence, however, that the aggregate supply of labor to the state and local sector is highly elastic and thus this bias is likely to be small.

[9] For example, we would expect the age distribution of the population to effect the relative importance to the decision makers of educational employment. Similarly population density will influence the relative importance of police employment.

[10] I also estimated a variant of (7) which substituted the category wage relative to the average wage for all state and local government employees in the state (W_j/W_T) for the category own wage (W_j). The estimates were similar in nature to those obtained using specification (7) and are omitted here for brevity. See Ehrenberg, chs. 4 and 5.

II. The Data

Published data allow us to consider eleven functional categories of employees and to pool time-series and cross-section information, with annual individual state data during the 1958–69 period as the units of observation.[11] Full-time equivalent state and local government employment has been reported by function and state since 1953, however the number of functional categories reported declined gradually from nineteen in 1969 to ten in 1953. Thus increasing the length of the time period under consideration can be done only at the expense of aggregating categories.

The choice of 1958 as the initial year was made on pragmatic grounds; by the availability of data on per capita federal grants to state and local governments. Referring to Table 1, this required that sewerage and other sanitation employment be aggregated into a sanitation category and financial administration employment be included with general control. Due to the similarity of functions performed by the two categories in each of these aggregate groups there appeared to be obvious reporting errors over time within several states (for example, the ratio of financial administration to general control employment in a state fluctuated widely over time, while the total of the two and their relative wage remained fairly constant). Hence both of these aggregations appeared to be desirable on a priori grounds. Finally, I constructed a miscellaneous all others category that included parks and recreation, correction, library, employment se-

[11] The variables used in the study are constructed from published data found in the U.S. government publications which are listed in the references.

curity administration, local utility, state liquor store, and all other state and local government employees not explicitly contained in any of the categories listed in Table 1.[12]

All of the variables expressible in dollar terms were deflated by the national consumer price index to obtain real values; unfortunately no individual state price indices exist and we were unable to control for interstate price differences. The average monthly payroll cost per man variable was derived by dividing full-time equivalent employment into total monthly payroll. In 1964 the reported full-time equivalent employment variable was rounded to the nearest 100 employees, which induced large errors in the wage variable for small states and/or relatively small functional employment categories. Consequently, data from 1964 was eliminated from the sample. Finally, no data was reported for Alaska or Hawaii in 1958 and 1959. The final sample thus consists of 546 state-year observations.

III. Empirical Estimates

This section presents estimates of the demand for state and local government employees. We first briefly discuss estimates of the derived reduced form model, when the minimum required employment level for each class is assumed to be zero, and consider the legitimacy of aggregating the data across years. Maintaining the same assumption, we next present estimates of the structural model utilizing the pooled data. Finally, the incremental budgeting model is estimated under a restrictive set of assumptions.

[12] For a description of the type of functions performed by employees in each category and an attempt to use a clustering procedure to determine the appropriate aggregated groups, see Ehrenberg, ch. 3. A more complete description of the methods of, and problems involved in constructing the variables utilized in the study is also found there.

Estimates of the Reduced Form and Tests for Aggregation Bias

Initially we assume that the minimum required employment level for each class of employees is zero; that the decision maker is free to choose the entire employment portfolio each period. Substituting (4) into (7) yields the reduced form system of demand equations. This system was estimated in three different ways by ordinary least squares: First, separately for each year in the sample using cross-section data. Second, using the pooled data for all years. Third, using the pooled data with a set of zero-one dummy variables included to allow the intercept term to vary over time.[13]

In general, the estimated coefficients of the economic variables in the individual year cross-sections, especially the wage elasticities, were statistically insignificant. In those cases that a particular coefficient was significant, it tended to vary widely across years. This clearly points out the dangers inherent in drawing conclusions from a single year's cross-section study.

As expected the estimates based upon the pooled data were vastly superior in terms of the signs and statistical significance of the key economic variables.[14] However one may question the legitimacy of aggregating the data across years. Using the sum of squared residuals obtained from the individual year and pooled regressions, F-statistics were calculated to test for the possibility of aggregation bias.[15] Specifi-

[13] The intercept dummy variables are included to capture intertemporal productivity variations, since if the productivity of state and local government employees varies over time, the demand for each category will also vary, *ceteris paribus*. Inasmuch as their inclusion did not significantly alter the estimated wage elasticities of demand, the intercept shift variables are not utilized in the subsequent analysis.

[14] For brevity, these estimates are not presented here since an analysis of them would be quite similar to that of the structural estimates.

[15] See Frank Fisher.

cally we consider two null hypotheses here:

(1) That the entire set of reduced form coefficients is identical across years for each category.

(2) That the entire set of reduced form coefficients except the intercept is identical across years for each category.

For six of the eleven functional categories the null hypothesis that the entire set of reduced form coefficients is equal across years was rejected. Furthermore, the rejection was not due solely to the intercept term varying; in four of these six cases null hypothesis (2) was also rejected.

For pragmatic reasons once again, we will continue to utilize the pooled data in what follows. However, our results must be qualified by noting that for about half of the categories information will be lost by the aggregation. Our simulations in the next section will be based in these cases upon estimated *average* elasticities which may differ from the marginal elasticities which we would obtain if significant coefficients could be derived from the individual year cross-section regressions.

Structural Estimates—No Incremental Budgeting

To estimate the structural model, we first estimate (4) to obtain an estimated per capita total employment budget ($\hat{B}/P$) and then use this as an instrumental variable in the estimation of (7). Moreover, if the employment budget is fixed, a positive residual in spending for one functional category must be offset by a negative residual in some other category. Due to the contemporaneous correlation of residuals across equations in (7), one would expect three-stage least squares estimates ($3SLS$) to be asymptotically more efficient than two-stage least squares estimates and the former method is used below.[16]

Utilizing the pooled data, estimation of (4) yielded the following (where the numbers in parentheses are absolute t-values).

$$\text{(8)}\quad \begin{aligned} \log(B/P) = &\underset{(21.48)}{-4.120} + \underset{(7.87)}{.315}\log(RW) \\ &+ \underset{(17.32)}{.222}\log(G/P) \\ &+ \underset{(28.60)}{.753}\log(Y/P) \\ &\qquad R^2 = .754 \end{aligned}$$

The less than unitary elasticity for RW indicates that, *ceteris paribus*, an increase in the average wage of public employees relative to private sector wages will cause a disemployment impact as the per capita total employment budget would increase by a smaller percentage. As indicated in Section IV, however, this impact may be partially offset if the resulting adjustments in the labor market lead to an increase in per capita income. Furthermore, to simulate the estimated impact on each category's employment level, requires estimation of the complete system.

The $3SLS$ estimates of (7) obtained under the assumption that the minimum required employment levels are all zero, are presented in Table 2.[17] The own wage elasticities are negative and statistically significant in all cases, save for the miscellaneous all other category.[18] Except for the public welfare category these elasticities are all significantly less than unity. Thus, as conjectured by many, the *partial* wage elasticities of demand for public employees do appear to be primarily inelastic.[19] Note however, that even the "essential services" police and fire protection have significant,

[16] Two-stage least squares estimates of (7) differed only marginally.

[17] The standard errors of these estimates are asymptotic estimates, hence the t-tests are only asymptotically valid and should be interpreted heuristically.

[18] Given the heterogeneous nature of the functions performed by employees in the latter category, the insignificant elasticity is not unexpected.

[19] They are partial elasticities because they do not consider the impact on the employment budget equation of an increase in a category's wage.

TABLE 2—3*SLS* ESTIMATES—POOLED DATA[a]
LOG-LINEAR EQUATIONS

General Control	−.316 (7.49)	.820 (19.53)	−.072 (14.23)		
All Other	.067 (1.18)	.740 (12.68)	.008 (1.16)		

Notes: M_j/P = per capita full-time equivalent state and local government employees of category j.
G/P = per capita federal grants to state and local governments, in real terms.
Y/P = per capita personal income in real terms.
B/P = per capita total employment budget for state and local government employees, in real terms.
W_j = average monthly payroll cost per full-time employee in category j, in real terms.
RW = ratio of average monthly payroll cost per man of all full-time state and local government employees to average monthly earnings of manufacturing production workers.
$SD1$ = population density
$SD2$ = proportion of the population ages 5–17.
$SD3$ = proportion of the population, age 65 and up.

Sources: Derived from data in U.S. Bureau of Census, *Estimates of the Population of States by Age*, CRP Series P-25 (various issues); *Government Finances* (various issues); *Public Employment* (various issues); *Statistical Abstract of the United States, 1969; Handbook of Labor Statistics 1970; Survey of Current Business* (Apr. 1965, Apr. 1970).

[a] The number of state-year observations for all equations is 546; 11 years (1958–63, 65–69) times 50 states minus the observations for Alaska and Hawaii in 1958 and 1959.

[b] Absolute t-values are shown in parentheses.

although small, wage elasticities of demand. The estimates of the per capita employment budget elasticities are all positive and statistically significant.

With respect to the sociodemographic variables, population density appears to be negatively related to education, highway, natural resource, and general control employment. The latter relationship may reflect the substitution of capital for labor that is possible in large scale clerical and administrative operations. This variable is also positively related to public welfare, hospital, police, fire, and sanitation employment. Several plausible factors relating to the relationship between population density and the costs and benefits from these services may explain the signs of these coefficients.

As expected, the proportion of the population between the ages of 5 and 17 is positively related to educational employment and the proportion of the population older than age 65 is positively related to public welfare and hospital employment. The negative relationship between the proportion of the population older than age 65 and health employment may be due to the preventive nature of many of the services in this category (for example, school immunization programs); services which are not directed primarily at the aged.[20]

Structural Estimates—Incremental Budgeting

To identify the α_k coefficients that appear in (7) requires either a method which allows non-linear constraints to be placed on parameters across equations or an iterative procedure. Software limitations prevented the former and to iterate over eleven coefficients searching for maximum-likelihood sets of estimates would have proven prohibitively expensive. Consequently, we adopt a second best procedure and assume that the minimum required proportion of last period's per capita employment level (α_k) is the same for all functions (α). While this assumption might be justified by arguing that all agencies apply equal pressure on decision makers to preserve their sizes, its main justification is in its analytic convenience.

Because the system (7) is log-linear, one cannot shift the $(\alpha M_j^{t-1}/P)$ variable in each equation to the right-hand side and thus the dependent variable will vary as α varies. Hence, we were unable to follow a procedure similar to that used by other investigators, of choosing the value of α which minimizes the sum of squared residuals in (7) across all eleven equations,

[20] Two extensions of the analysis that were conducted warrant brief reporting: First, regardless of whether state and local government decision making is actually governed by an explicit utility maximization framework, it seems desirable to use an econometric approach in which the sum of the estimated payroll expenditures across categories adds up to the estimated total employment budget. This can be expressed as the Engel aggregation condition, that the sum of the per capita employment budget (B/P) elasticities of demand, weighted by their respective category proportions of total payroll expenditures, be unity. Formal F-tests of this restriction for the estimates of (7) reported in Table 2, utilizing 1969 national average category expenditure weights, indicated that the weighted sum was significantly less than unity. Consequently, the system (7) was reestimated using a restricted 3*SLS* technique (see Henri Theil), with the Engel aggregation condition imposed as a constraint. The restricted wage elasticities of demand differed only marginally from the unrestricted estimates, except the elasticity for educational employment which doubled in magnitude. The employment budget elasticity for education also increased substantially; intuitively this was expected to occur as the expenditure weight on education is over 50 percent. The employment budget elasticities for the other categories increased only marginally.

Second, the dangers inherent in inferring time-series responses from pooled cross-section time-series data are well known. While the lack of degrees of freedom generally led to statistically insignificant coefficients when the system (4), (7) was estimated *separately* for each individual state using the short time-series 1958–63, 65–69; these statistically insignificant individual state time-series coefficients were used to perform nonparametric tests to ascertain if the wage elasticities of demand for each category appeared to be "primarily" negative as postulated. Such tests (Ehrenberg, ch. 4) supported this hypothesis for most of the categories. See Alexander Mood and Franklin Graybill, p. 403–25 for the basis of the nonparametric test used.

[c] Absolute t-values in parentheses.

time periods and states.[21] Rather, 3SLS estimates of the system were derived for a set of values of α and it was heuristically determined that the minimum required proportion (α) lies in the range 0.0 to 0.5.[22] For values of α which fall in this range, *disemployment effects* of postulated future relative wage increases are simulated in the next section. Since these estimates are tolerably stable over the range of values, it is unnecessary for us to choose a "statistically optimal" estimate for α.

For comparison purposes, estimates of (7) when α was assumed to equal .5, are presented in Table 3.[23] In general as α increased from 0 to .5, the employment budget elasticities decreased; however, there was no uniform pattern of change for the own wage coefficients.

[21] See, for example, Stone.

[22] The system (7) was estimated as α varied from 0.0 to 0.9 in steps of 0.1. Two criteria were used in our

IV. Implications For Public Policy

The impact on per capita full-time equivalent state and local government employment in each functional category of an increase in the category real wage can be simulated using the parameter estimates described in the previous section. We consider two cases here:[24]

A. The real wage of a functional category of state and local government employees increases relative to all other employees' real wages and nonlabor real personal income.

B. The real wages of all state and local government employees increase proportionately, relative to all other employees' real wages and nonlabor real personal income.

For both cases, we calculate the *total* own wage elasticity of demand for each functional employment category, which consists of two components. First, the direct *partial* elasticity, based upon the estimated own wage (W_j) elasticities obtained from the individual category employment demand equations. Second, the indirect effect, which operates through the impacts of an increase in the class wage on the relative cost of publicly to privately produced services (RW) and on per capita personal income (Y/P) in the per capita total employment budget equation. Since the per capita total employment budget (B/P) tends to increase due to these impacts, as long as an employment category has a positive employment budget elasticity, its total wage elasticity will be smaller in absolute value than the partial elasticity.[25] Moreover, *ceteris paribus*, the larger the partial wage elasticity, the smaller the employment budget elasticity, and the smaller the share of the total employment payroll spent on the category, the larger in absolute value will be the total wage elasticity. Hence, the larger will be the disemployment impact that would result from an increase in the class wage.

Differentiating the system (4), (7) with respect to the real wage of each class, one can derive formulae for the total own wage elasticities of demand for the two cases considered.[26] In addition to the parameter estimates obtained from the estimation of (4) and (7) these elasticities are seen to depend upon the fraction of the employment budget initially spent on each category, the proportion of personal income earned by state and local goverment employees, the ratio of per capita total state and local government employment lagged

heuristic evaluation of which values of α yielded plausible estimates. First, as observations were eliminated from the sample when $M_j/P-\alpha M_j^{t-1}/P$ was negative for any category, what proportion of the original number of observations remained in the sample for each value of α? Second, for each value, what proportion of the wage and employment budget elasticities were statistically significant and of the anticipated sign? Details of this analysis are also found in Ehrenberg, ch. 4.

[23] It is easily seen that b_{1j} and b_{2j} in (7) represent the steady-state wage and employment budget elasticities, respectively.

[24] Several additional cases are considered in Ehrenberg, ch. 5.

[25] An increase in state and local government employees' wages would lead to the following set of adjustments in the labor market; a decline in state and local government employment (the impact which we seek to estimate) and an increase in the level of unemployment and/or an increase in the supply of labor to the private sector, resulting in lower wages but greater employment there. To the extent that private sector wages and employment do not change (perhaps due to wages which are inflexible in a downward direction), per capita personal income would increase as long as the demand for state and local government employees is wage inelastic. Our simulations ignore the adjustments that would occur in private sector wages and employment (i.e., they assume a private sector wage elasticity of unity), and may to a minor degree overstate the impact of public employee wage changes on per capita personal income As a consequence, the total elasticities presented in Table 4 may be slightly biased towards zero. However, since the partial elasticities provide an absolute upper bound for the total elasticities, our main conclusions would be unaltered. The simulations also assume that per capita federal grants are unrelated to state and local government employees' wages.

[26] The formulae and their derivations are available upon request from the author.

one year to the current total, and the comparable ratio for per capita employment in each category. National average values for each of these variables in 1969 are used in the simulation.

Substitution of these values and the necessary parameter estimates obtained from the estimation of (4) and (7) into the derived formulae, yields empirical estimates of the total own wage elasticities of demand. These are calculated for seven different sets of estimates of (7).[27] In Table 4, for each functional category and case, we indicate the interval over which the seven sets of estimates varied. It should be emphasized that these do *not* represent statistical confidence intervals, rather they indicate only the sensitivity of the total elasticities to the value of α utilized. The short-run elasticities reported in Table 4 refer to the impact in the first year, while the long-run elasticities indicate the steady-state solutions. The two are identical when $\alpha=0$.

Considering first case A, in which employees in a functional category succeed in pushing up their real wages relative to all other employees and nonlabor personal income, the estimates appear to be tolerably stable for each category, except education and public welfare. Moreover in all cases, save perhaps public welfare, there is no doubt that the total own wage elasticities are *inelastic*. A 5 percent increase in the real wage of a class would, *ceteris paribus*, decrease *per capita* full-time equivalent in the class by less than 5 percent. Furthermore, since population growth has averaged more than 1 percent a year, the category decline in *total* full-time-equivalent employment would be even smaller.

Due to the fact that an increase in any class wage increases the sum of the committed employment expenditures, all partial cross-wage elasticities of demand are negative in the short-run for case A. However, in most cases the magnitudes of these partial cross wage-elasticities are extremely small, often less than $-.001$.[28] Furthermore, when we consider the indirect impacts through the total employment budget equation, the short-run total cross-wage elasticities are seen to be primarily positive and in the long-run they are all positive.

Turning to case B, in which all state and local government employees' real wages increase proportionately relative to all other employees' wages and nonlabor personal income, the estimated disem-

[27] These estimates correspond to values of α assumed equal to 0 (Table 2), 0—restricted estimates, .1, .2, .3, and .4 (all not presented here for brevity), and .5 (Table 3).

[28] For example, when $\alpha=.5$, only 6 of 110 partial cross-wage elasticities of demand were greater than .1 in absolute value with all referring to employment responses to changes in the education wage.

ployment effects are now all smaller. Inasmuch as a proportionate state and local government employee wage increase removes the incentive to substitute across functional categories, this result was exexpected. Those elasticities that remain negative are all inelastic; however, several of the intervals now contain zero and a few of the estimated elasticities are even always positive. For example, in the long run, police, fire, general control, and the miscellaneous all other category, all appear to have positive total wage elasticities of demand.

These results suggest that while state and local governments do respond to market forces in choosing their employment portfolios, these market forces do not appear to be sufficiently strong to limit the size of real wage increases which state and local government employees may seek in the future. They also suggest that employees in each functional category have a stake in the economic well-being of members of all the other categories, as each category can minimize the potential employment losses of their members by seeking to increase the real wages of all categories, rather than merely their own real wage. Consequently, continual careful consideration, on both sides, should be given to the evolving structure of collective bargaining in this sector.[29]

[29] The estimates of (4) and (7) can also be used to simulate the impact of public sector employment programs (such as that contained in the *Emergency Employment Act of 1971*) in which the federal government makes cash grants to state and local governments in an attempt to increase the number of public sector jobs. Ehrenberg, ch. 5, presents such a simulation.

Quarterly Models of Wage Determination: Some New Efficient Estimates

By J. C. R. ROWLEY AND D. A. WILTON*

The concept of stable Phillips curves and their economic implications have been the subject of a series of disputes in recent years. Since Phillips introduced his simple disequilibrium model, empirical research in the field of wage determination has indicated a wide spectrum of explanatory variables which expands and contracts almost randomly in published studies. Apart from this difficulty in specification, the intertemporal instability of estimated coefficients for Phillips curve variants is particularly disturbing.[1] In addition, the theoretical bases for many of these variants are unclear and several economists have participated in a neoclassical counter-attack on the existence and stability of Phillips curves from a theoretical viewpoint.[2]

The objectives of this paper are to examine the consequences of certain invalid statistical procedures which are employed in many of these studies and to provide some empirical evidence of their effect. In particular, we focus attention on the implications of the aggregative procedure which provides the basis for the use of a "four-quarter overlapping change" representation of the dependent variable in quarterly studies of wage determination and, also, for the use of moving-averages of explanatory variables. A partial list of studies which make use of these specifications would include the following works: Paul Anderson, Ronald Bodkin et al., George de Menil, Leslie Dicks-Mireaux and Christopher Dow, Otto Eckstein, Michael Evans and Lawrence Klein, John Helliwell et al., Klein and James Ball, Edwin Kuh, Michael Levy, Richard Lipsey and Michael Parkin, George Perry, Edmund Phelps, Gale Pierson, Grant Reuber, Charles Schultze and Joseph Tryon, Norman Simler and Alfred Tella, and Wayne Vroman.

Although these forms of variables are predominant in many studies, the implications of the aggregative procedure for the error terms are usually either completely neglected or represented by simple statements of "possible" problems which are not discussed further.[3] Kuh's assertion that " . . . artificial serial correlation is often introduced through the overlapping process which partially neutralizes the confidence to be placed in the larger t-coefficients" (p. 346) is rare in its explicit reference to the problem of autocorrelation. In the first section of the paper we present a set of assumptions sufficient for

* Economic Council of Canada and Statistics Canada, respectively. We are indebted to the Canadian Department of Labour for research support and to the Institute for Economic Research at Queen's University.

[1] For example, in our attempts to reproduce the estimates of the study by Bodkin et al., we mistakenly added two additional observations to our initial sample. The estimated coefficient of the unemployment term increased from 10.4 to 17.3. For further evidence of the inherent temporal instability of Phillips curve variants, see Levy and Perry, pp. 72–84.

[2] See the studies by Phelps et al.

[3] There are exceptions. For example, see Dicks-Mireaux and Dow, Sparks and Wilton, and Sargan. In addition, Kuh and Eckstein present models with both quarterly and overlapping annual changes in wage-rates which indirectly illustrate the nature of the problem. The use of quarterly changes reduces the problem of autocorrelation which we shall illustrate but introduces other difficulties. Student's t-statistics are much lower for models of quarterly changes than for the models of overlapping annual changes.

the specification of the "four-quarter overlapping-change" model in wage analysis. Serial correlation in the error term is shown to be a necessary consequence of the model. However, if the collective explanatory variables can be calculated, then generalized least squares (*GLS*) estimators can likewise be calculated for the coefficients as well as ordinary least squares (*OLS*) estimators. These two sets of estimators provide the data for our assessment of the effect of the aggregative procedure.

Necessary and sufficient conditions for least squares estimators to be fully efficient despite the presence of autocorrelation, so that both standard errors and Student's t-statistics are unaffected by it, have been established by William Kruskal, Sujit Mitra and C. Radnakrishna Rao, Rao (1967, 1968) and George Zyskind (1962, 1967). These statistical results need to be supplemented in particular analyses by empirical results since they indicate that optimality of least squares procedures may depend upon both the particular sample to be used and the weights adopted for the aggregative procedure. If the least squares estimates of coefficients are not optimal, conventional estimates of standard errors and Student's t-statistics are based on inappropriate formulae. However, the parametric estimates remain unbiased and the inaccuracies of these formulae may be small. Their extent must be established empirically, although Benee Swindel and Geoffrey Watson (1955, 1967) provide theoretical accounts of bounds on these inaccuracies. Three tables, which contain *OLS* and *GLS* results for three different studies of wage determination, reveal that the use of these formulae leads to substantial errors in inference.

As a basis for discussion, the study by Perry provides an appropriate framework since it is one of the earliest and, perhaps, best elucidated studies on the use of overlapping annual changes in the context of quarterly data. We have presented a complete analysis of the general model of discontinuous wage changes elsewhere (1971) so only a brief statement of the set of sufficient conditions for the four-quarter overlapping change model will be presented below. Most of these assumptions are either explicitly or implicitly stated by Perry (pp. 30–31).

I. The Model of Wage Determination

(A1) Wages are set annually for all workers, and, once established, remain fixed until the next annual negotiation and settlement.

(A2) The labor force is divided into four distinct groups on the basis of the quarter in which their annual wage negotiations and settlements take place.

(A3) The ratios of all seasonal groups in the labor force to the total labor force are constant.

(A4) The percentage change in wages for each of the four seasonal groups is a function of the same set of explanatory variables with the same parameter values for each group. Explanatory variables (X) and error term (u) are dated in the quarter in which the wage negotiation and settlement took place (j). That is,

$$\frac{w_j^h - w_{j-4}^h}{w_{j-4}^h} = aX_j + u_j$$

for $h=1, \ldots, 4$ and $j=h+4s$, where s is an integer and w_j^h is the wage rate for the hth group in the jth quarter.

(A5) The relative change in the aggregate wage rate is appropriately approximated by a moving average for the relative changes in the wage rates of the four groups. The weights of this moving average are assumed to be equal,[4] where

[4] Critical discussions of this assumption are provided by Rowley and Wilton (1972b), *Int. Econ. Rev.*, forthcoming.

w_t is the aggregate wage rate.

$$\frac{w_t - w_{t-4}}{w_{t-4}} = \sum_{h=1}^{4} 0.25 \frac{w_t^h - w_{t-4}^h}{w_{t-4}}$$

For statistical purposes, the model is completed by the specification of a list of explanatory variables and a distribution for the error term. Ignoring this latter ingredient, the final equation is the familiar one, with the overlapping annual wage change form of the dependent variable and fourth-order moving averages for the explanatory variables. However, the error term is likewise distributed as a moving average process with the same known weights.

$$\frac{w_t - w_{t-4}}{w_{t-4}} = a\left(\sum_{i=0}^{3} 0.25\, X_{t-i} \right) + \sum_{i=0}^{3} 0.25\, u_{t-i}$$

Let $\{u_t\}$ be a sequence of normally distributed errors which are mutually independent and have constant, equal variances. With this additional assumption and the knowledge of the known weights, the method of generalized least squares can be employed to calculate efficient estimates of the coefficients of the explanatory variables. As shown in our Appendix, knowledge of the weights indicates a transformation which can be used to adjust the equation so that the problem of autocorrelation is eliminated.[5] Then, the appropriate estimates of the standard errors of estimated coefficients (based on unbiased estimates of their variances) and Student's t-statistics can be calculated.

In the absence of this adjustment, the *OLS* method yields biased estimates of standard errors and invalid Student's t-statistics unless the sample fulfills the conditions given in the references cited above. Calculation of *GLS*[6] estimates permits us to observe how badly the *OLS* estimates are for the hypothetical model with a given sample. Note that even if this distribution of $\{u_t\}$ is inappropriate, as would be the case if the original errors for individual groups were autocorrelated, the results would remain of interest since they reveal the sensitivities of estimates to different specifications of the distribution for errors.[7] Finally, notice that the aggregate error is not generated by a first-order autoregressive process so the Durbin-Watson statistic is not an appropriate indicator of serial correlation and applications of the popular Hildreth-Lu procedure "to correct for serial correlation" will not do so in fact.[8]

II. Empirical Results

Results for the model of Perry are supplemented below by additional estimates for the model of Bodkin et al. and the wage equation contained in the econometric model (*RDXI*) of the Bank of Canada.[9] The role anticipated for these supplemental results stems from the danger that the inadequacies of empirical results for a single study might prove atypical. Although the use of three studies cannot eliminate this danger, we can

[5] A more detailed account is provided by Rowley and Wilton, *Metroeconomica*, forthcoming.

[6] *GLS* estimates are seldom calculated even if we have precise knowledge of the process generating the errors because of their computational burden. J. H. Wilkinson demonstrates how this burden can be substantially reduced by the efficient Cholesky technique in our particular case of a moving average.

[7] Rowley and Wilton (1972c) indicate suitable approaches in the context of alternative distributions of the errors and wage-spillover effects between different micro-groups.

[8] Empirical evidence on the loss of efficiency which stems from this procedure is presented by Rowley and Wilton (1972a).

[9] Our choice of studies was affected by our background and by the accessibility of data. In the latter regard, we wish to thank the Bank of Canada and Steve Kaliski for making data available to us. Both of the additional studies employ different wage data and time horizons from the study by Perry.

present conclusions with greater confidence than would be the case with a single study.

Each of the following three tables are divided vertically into two sections. The first section contains *OLS* estimates based on inappropriate formulae for standard error and Student's t-statistics (columns (1), (2), (3) for Table 1, columns (1), (2), (3), (4) for Table 2 and column (1) for Table 3), whereas the second section contains the appropriate *GLS* estimates on the assumption that the errors follow the distribution cited. Student's t-statistics are presented in parentheses below each estimated coefficient. To clarify exposition, the calculated numbers for the *OLS* estimates of Student's t-statistics are prefixed by the term "pseudo" since we have reason to believe that they are based

on biased estimates of variances and on a misspecification of the distribution for the errors.

Two questions should be considered while the empirical results are read. First, would the set of *OLS* estimates lead the (typical) economist to draw invalid inferences with respect to the significance of variables in the models. Second, if these invalid inferences are drawn, are they sufficiently severe to suggest that the additional burden of computation for the

Dependent variable = Annual percentage change in the average hourly wage in the private sector $[(W_t - W_{t-4})/W_{t-4}]$

$\dot{P}_t$ = four-quarter moving average of the annual change in the implicit price index of consumer nondurable expenditure

$$\frac{1}{4}\sum_{i=0}^{3}\frac{P_{t-i} - P_{t-4-i}}{P_{t-4-i}}$$

$1/U_t^2$ = squared reciprocal of a four-quarter moving average of the unemployment rate.

R_t = four-quarter moving average of the ratio of corporate profits before taxes (less income tax accruals) to real gross national expenditure.

$\dot{W}_{t-4}$ = dependent variable lagged four quarters.

[a] Pseudo t-statistics are shown in parentheses.

[b] t-statistics are shown in parentheses.

GLS estimates is worthwhile.

Looking only at the *OLS* estimates in these three tables, one would conclude that these Phillips curve variants perform reasonably well. The three common explanatory variables, unemployment, price increases, and profitability, are pseudo-significant in all cases save one (the unemployment variable in equation (1) of Table 2). With the possible exception of the Durbin-Watson statistic, all of the conventional statistical checks are satisfied, i.e., sign patterns, Student t-statistics greater than two, etc.

On the other hand, statistical inferences drawn from the *GLS* equations are largely inconclusive. While F-tests indicate that in all cases the joint hypothesis that all coefficients for explanatory variables are zero must be rejected (since critical .05 values for the F-statistic fall within the 2.4–3.5 range), the results for individual explanatory variables are not encouraging. Only the profit variable retains significance in even half of the *GLS* equations. Unemployment and price increases, perhaps the two most common explanatory variables in all wage research, are significant in only two of eight individual cases. One can only speculate whether the various authors would have advanced the Phillips curve model had they been faced with the *GLS* estimates rather than the *OLS* estimates.

Turning from individual explanatory variables to a comparison of the three studies, the Perry model holds up best under *GLS*, but again the results are not that encouraging. While all variables are pseudo-significant under *OLS*, there is no consistent pattern for variables under *GLS*. No variable's coefficient retains significance in each of the three sectors. The basic Phillips curve variable is significant in only one sector while price and profit variables are significant in two of three sectors. In sectoral terms, no one equation exhibits significant coefficients for all four explanatory variables.

The *GLS* results for the two Canadian studies are perhaps more conclusive. None of the usual explanatory variables would appear to be reliable from usual statistical tests. In place of fifteen pseudo-significant coefficients in the Bodkin et al. study, only three parameter estimates are

significant under *GLS*. Their basic model, as represented by equations (1) and (5) in Table 2, fails to retain one of the five pseudo-significant parameters. As shown in Table 3, all explanatory variables in the *RDXI* wage equation likewise prove to be insignificant under *GLS*, again a revealing contrast from the *OLS* results. The only consolation rests with the *F*-statistic, even though it is greatly reduced under *GLS*. As a group the explanatory variables are significant at the .05 level.

In short, the potential bias in estimated Student's *t*-statistics using conventional *OLS* techniques appears to be substantial. Employing the *GLS* technique, which produces unbiased estimates of the variances of estimated coefficients, all standard error estimates exceed those obtained using *OLS* with more than two-thirds of the individual coefficient standard errors increasing by more than 100 percent. In terms of standard significance tests, the results are even more pronounced. All Student's *t*-statistics fall under *GLS* as *OLS* pseudo-*t*-statistics are at least twice as large for over three quarters of all parameter estimates and at least three times as large for more than half of the parameter coefficients.

Two final comments can be made concerning the estimates. Since both *OLS* and *GLS* give unbiased parameter estimates, one might expect our coefficient estimates to be reasonably similar for both estimation techniques. Almost two-thirds (20 of 32) of the *OLS* parameter estimates are within one standard error of the *GLS* estimates. Finally, the appropriateness of the Durbin-Watson statistic is somewhat dubious. As pointed out above, it fails to test for a fourth-order moving-average process in the error term, as exists in the *OLS* equations. While the Durbin-Watson statistics are close to two under *GLS*, a fourth-order autoregressive pattern would appear more plausible as an alternative hypothesis in view of the annual bargaining patterns in the four distinct labor groups.

III. Conclusion

A necessary first step in empirical research is the specification of the form of the dependent variable, that is, the sequence of values which are to be explained. Quarterly analyses of wage determination have adopted overlapping annual changes as the appropriate form of their dependent variable. Explicit recognition of the statistical implications of this choice is extremely rare. We have presented a set of assumptions which are sufficient to explain this particular specification for the dependent variable. Serial correlation in the error term is a direct consequence of the aggregative procedure indicated by these assumptions. In particular, if researchers specify the same moving average for all explanatory variables, then the aggregate error must exhibit the same moving average features. Hence, all of the conventional formulae for appropriate standard errors and test statistics are potentially biased, with the extent of biases to be determined empirically.

For the three models which we have considered, these biases are shown to be substantial. A comparison of Student's *t*-statistics based on correct formulae with the pseudo-results suggest that the latter must be reduced by at least 50 percent in most cases. The inferential consequences of these reductions are severe and cannot be neglected. The roles of certain variables, which are usually considered to be of major importance in the determination of wage levels, are in doubt. For example, in the eight equations for which *GLS* estimates are calculated, unemployment is significant at the .05 level twice and not seven times as indicated by the results for the conventional *OLS* procedure. Similarly, the change in prices is significant

twice at this critical level although the *OLS* results indicate eight times.

While there are dangers in attempts to generalize these results which are based on only three studies, every test indicates the potential severity of the problem of unacknowledged serial correlation.[10] Fortunately, as we have demonstrated, there are simple ways to correct for this bias in estimation. Correctional techniques require few additional assumptions other than those which already form the bases for specifications of the dependent variable and moving averages of the explanatory variables. Only after these corrections are made will economists be able to assess the true significance of the alternative theories which have been advanced to explain the determination of aggregate wage changes.

Appendix

The collection of error terms $\{u_t\}$ from the equations for the individual labor groups is assumed to form a temporal sequence of normally distributed random variables with zero means. This sequence is assumed to be free from autocorrelation and heteroscedasticity[11] so that attention may be solely focused on the specific problem introduced by the aggregative process, which indicates a sequence of moving-average aggregative errors, $\{e_t\}$ say. Thus, from (A5), we have the following definition.

$$(1) \qquad e_t \equiv 0.25 \sum_{i=0}^{3} u_{t-i} \qquad \text{for all t}$$

Since the individual errors have zero means and the weights for aggregation are non-stochastic, the aggregative errors have zero means and their autocovariance function can be represented by mean products of the form $E(e_t e_{t-s})$ where $E(\cdot)$ represents the mean or mathematical-expectation operator. Due to our stationarity assumptions, the products will only depend on the lag s between the individual errors and can be denoted as γ_s.

$$(2) \quad \gamma_s \equiv E(e_t e_{t-s}) \qquad \text{for all } s, \text{t}$$
$$= 0.0625E\left[\left(\sum_{i=0}^{3} u_{t-i}\right)\cdot\left(\sum_{j=0}^{3} u_{t-j-s}\right)\right]$$

$$(3) \quad \gamma_s = 0.0625 \sum_{i=0}^{3}\sum_{j=0}^{3} E(u_{t-i}u_{t-j-s}) \qquad \text{for all } s, \text{t}$$

In view of the assumptions with respect to autocorrelation and homoscedasticity which were made explicit above, this expression can be simplified. Let σ^2 represent the common variance of the individual errors and we have

$$(4) \quad \gamma_s = 0.0625\,(4-s)\sigma^2 \quad \text{for } s = 0, 1, 2, 3$$

$$(5) \quad \gamma_s = 0 \quad \text{for } s > 4$$

$$(6) \quad \gamma_s = \gamma_{-s} \quad \text{for all } s$$

Thus, the autocovariances $\{\gamma_s\}$ are known apart from the scale factor σ^2 and the dispersion matrix of the aggregative errors can be constructed. This is a Laurent matrix with a narrow band of positive elements about its principal diagonal representing the Yule-Slutsky effect of the aggregative process:

$$0.0625\sigma^2 \begin{bmatrix} 4 & 3 & 2 & 1 & & & & 0 \\ 3 & 4 & 3 & 2 & 1 & & & \\ 2 & 3 & & & & & & \\ 1 & & & & & & & \\ & 1 & & & & & & 1 \\ & & & & & & & 2 \\ & & & 1 & 2 & 3 & 4 & 3 \\ 0 & & & & 1 & 2 & 3 & 4 \end{bmatrix}$$

Knowledge of this matrix (apart from the scale factor) is sufficient for the generalized least squares estimates to be calculated. See,

[10] Since this paper was originally drafted, we have reestimated other models with similar results. For example, only one of seven unemployment coefficients retains significance at the .05 level in *GLS* estimates for equations (2)–(5) in Pierson.

[11] Clearly the influences of many other factors are being ignored and these may confound the empirical results. We are, for example, ignoring the potential problems associated with errors in measurement, stochastic weights and simultaneity.

for example, the descriptions by Jack Johnston, pp. 208–11, and Arthur Goldberger, pp. 231–35. These indicate an appropriate transformation for the model which is based on a factorization of the dispersion matrix and its inverse. In practice, inversions of large matrices must be efficiently computed so that numerical errors do not distort the resultant numbers. The Cholesky technique for inversion is especially recommended in this context since it takes account of the symmetry and "bandedness" of the matrix. An account of this technique is provided by J. Wilkinson.

Quit Rates Over Time: A Search and Information Approach

By Donald O. Parsons*

Recent developments suggest that important insights into the nature of the labor market can be gained by following an information and search approach.[1] A quit rate model is developed and estimated below which integrates two major informational factors. George Stigler's seminal work (1962), later systematically restated by Reuben Gronau using a more appropriate sequential decision process, assumed that workers know their alternative wage distribution but not particular wage bids. The worker's optimizing problem, then, is the search for wage bids. Armen Alchian and others have found it useful to consider the worker's process of estimating the wage distribution parameters as well, since these are not known to the worker either. Alchian hypothesizes that a worker's estimate of his alternative wage possibilities will lag behind actual conditions in a changing world. In terms of the quit rate considered here, a worker will quit less frequently than real conditions warrant during inflationary times (at least until he becomes adapted to a given rate of inflation) because he knows immediately when his own wage rises, but discovers only after some time that the wage rates of others have also risen. Optimizing models for these two distinct informational processes are derived in the next two sections and integrated into a quit probability model useful for econometric work.[2]

The parameters of the quit rate model thus derived are then estimated from monthly time-series data over the period 1959–68 for twenty-seven 3- and 4-digit manufacturing industries. The estimates appear to confirm the importance of the "real" search factors initially considered by Stigler. The vacancy rate or probability of getting a job offer has a strong impact with a very short lag time, while relative wages have the expected effect, although with longer lags and less regularity. Alchian's expectation hypothesis, however, receives little empirical support. The effect of nominal wage changes had no systematic effect on quit rates when the "real factors," vacancy rates, relative wages, etc., were controlled. In this respect, workers seem well attuned to demand conditions and there is no evidence that any wage rate illusion, whether optimally motivated or otherwise, poses a serious market problem.

I. The Optimal Job Search Strategy

In this paper, it is assumed that the worker attempts to maximize his expected income in a world where wage dispersions exist for workers of comparable skills both because information costs relative to

* Assistant professor, Ohio State University. Useful remarks and criticism by Lester Telser, H. Gregg Lewis, Belton Fleisher, and members of the labor workshops at the University of Chicago and Ohio State University are gratefully acknowledged.

[1] Beyond the seminal papers by George Stigler (1961, 1962), the works of Armen Alchian, Charles Holt, John McCall, Dale Mortensen (1970a, b), and Reuben Gronau are relevant here. The firm aspects of this process, emphasized by Holt and Edmund Phelps and beautifully integrated with the worker aspects into a complete market model by Mortensen (1970a), are largely ignored here.

[2] These two types of information gathering correspond to some degree to the extensive and intensive search dichotomy suggested by Albert Rees.

returns make perfect information uneconomical and because job transfer costs make even known higher wages sometimes uninteresting. Consider first the labor market demand conditions which will justify searching for an alternative job. Since, at each unit of search, the costs and returns to further search will be influenced by offers already received, the number of units of search will not usually be specified in advance, but will be determined sequentially. The worker must decide at every step whether incremental returns exceed incremental costs if he is to undertake what is for him the optimal amount of search activity.[3]

In determining the return to a unit of search, the worker is faced with a certain probability that the firm will not be hiring at all[4] and with a distribution of possible wage offers (which we shall assume is normal with mean $\overline{W}_A$ and variance σ_A^2) from firms which are hiring. Interpreting a "no job offer" search result as a zero wage offer, the expected return to a unit of search (R_i) will be the probability of a nonzero wage offer times the expected wage increase net of transfer costs, or

$$(1) \qquad R_i = \text{prob}\,\{\text{offer} \mid \text{search}\} \cdot E\{NWI \mid \text{offer}\}$$

The probability of a nonzero wage offer will presumably be an increasing function of job vacancies (v), say $g(v)$[5] where $\partial g(v)/\partial v > 0$. The expected net wage increase (NWI) will depend on the worker's present wage (W_0), his transfer costs (TC), and the parameters of the alternative wage distribution. In particular,

$$(2) \qquad E\{NWI \mid \text{offer}\} = \int_{W_C}^{\infty} (W_A - W_C) f(W_A)\, dw_A$$

where the critical wage $W_C \equiv W_0 + TC$, and $f(W_A)$ is the normal density function of alternative wages. Below the critical wage W_C, of course, wage offers have no economic value to the worker. When integrated, equation (2) becomes

$$(3) \qquad E\{NWI \mid \text{offer}\} = \sigma_A^2 f(W_C) - (W_C - \overline{W}_A)[1 - F(W_C)]$$

where $F(W_C)$ is the cumulative normal distribution.[6] The partial derivatives of the returns to search with respect to v, W_C, $\overline{W}_A$, and σ_A are as follows:

$$(4) \qquad \partial R_i/\partial v = \frac{\partial g(v)}{\partial v} \cdot E\{NWI \mid \text{offer}\} > 0$$

$$(5) \qquad \partial R_i/\partial W_C = \partial R_i/\partial W_0 = \partial R_i/\partial TC = -\,g(v)[1 - F(W_C)] < 0$$

$$(6) \qquad \partial R_i/\partial \overline{W}_A = g(v)[1 - F(W_C)] > 0$$

$$(7) \qquad \partial R_i/\partial \sigma_A = g(v)\sigma_A f(W_C) > 0$$

For given search cost, search by employed workers will rise when demand conditions improve and more potential employers are hiring workers.[7] Intuition suggests that this will be the most volatile component of the return structure. Search returns will also increase, as one would expect, when the worker's wage is low relative to his alternative wage. The second derivatives of equations (5) and (6) imply that the impact on search returns of a change in

[3] This rule, of course, ignores the possibility of initially decreasing costs of search.

[4] Since workers on the payroll already have processing and training investments made in them, job seekers must vie for new positions rather than compete directly with the employed. Future hiring costs will also be higher if a firm gets a reputation for handling its experienced workers poorly.

[5] Stigler (1962, p. 101) asserts the "no offer" probability will also be dependent on the ease of identifiability of the firm and other factors.

[6] An appendix containing a proof of this integration and of the partial derivatives to follow is available upon request from the author.

[7] The same rule should apply to unemployed workers as well, although total worker search efforts may increase in bad times since unemployed workers will tend to search more in general than employed workers.

wage diminishes the higher the relative wage. Equation (7) and its second derivative imply that an increase in the alternative wage dispersion will increase the returns to search,[8] with the effect strongest among workers with critical wages near the mean of the alternative wage distribution.

The total amount of search undertaken will depend, of course, on search and transfer costs as well as on the probable wage offers he will encounter. Presumably such costs will increase at an increasing rate, if only because of the geographic dispersion of employers. Below, this search cost function is approximated by a quadratic in search units. The wider the search, the less information is available on prospective employers, which again suggests rising marginal search costs. This cost function is assumed to be regenerative between periods since the worker can visit the same prospective employers repeatedly at the same cost per visit. Search costs will vary over the business cycle, since firms are likely to increase their supplies of new workers by reducing worker search and transfer costs. This can be accomplished by increasing advertising, arranging convenient interview times, paying moving expenses, etc., as well as by offering higher wages. Worker search costs per unit of search should decline when general demand conditions improve.

The worker who believes search for another job will be profitable is confronted with a choice of search techniques. He may quit as soon as he is convinced search is useful, or he may remain employed, searching after work hours or on days off, in which case he will quit only if he encounters a sufficiently favorable wage. Which option is chosen will affect the quit probability of a given worker and will also affect the lag structure of quits behind changes in market conditions. If workers quit when the decision to search is made, the lag will be in recognizing the new conditions more favorable to search. If workers remain employed, however, the quit lag will involve the search lag as well as the recognition lag.

The decision to quit to search or to remain employed is a complex decision involving the evaluation of two sequential programming problems. Both the search cost and search return functions will be altered by the decision to quit to search. The opportunity costs of time will be approximately equal since one approach sacrifices income possibilities while the other sacrifices leisure which should be approximately equal in value at the margin. The search cost function of the unemployed searcher will be lower to the extent economics of scale are possible because larger blocks of time are available. A salesman's transportation costs, to look at a comparable situation, will surely rise the more frequently he is required to return home for supplies. This consideration suggests workers will be more likely to quit to search the more geographically isolated they are from other areas of labor demand and the less flexible are their hours and work days.

Search returns will be similarly affected by the decision to quit to search. The risk factor is surely greater since the worker might well end up with a job paying less than his present wage. The stigma of being a quitter may also reduce the expected returns to a given quantity of search. In deciding which workers to hire (which implies a decision to invest in these workers), firms will attempt to increase their returns by choosing workers with a low quit propensity and may look with disfavor on unemployed quitters. One positive aspect on the returns side, which

[8] If wage dispersions have narrowed with improved communications, and transportation, as Stigler (1962, p. 98) believes, search efforts per worker should show a secular decline.

will increase the incentive to quit to search, is the likelihood that the higher wage from successful search will be captured more quickly if the worker concentrates his search by quitting.

Fortunately, scraps of empirical evidence allow us to avoid the detailed empirical analysis required to predict the proportion of workers who quit to search. Two national surveys of labor mobility seem to indicate that the great bulk of quitters search while employed and quit only if they have another job lined up. The surveys, conducted in 1955 and 1961, found that of those workers who undertook only one job change during the year and did so to "improve status," about 80 percent experienced no unemployment.[9] The quit model developed below assumes that workers quit only when a preferable job is uncovered, although the interpretation of the empirical results varies only slightly if this proposition is relaxed.

The timing of the quit decision will depend on which jobs are deemed preferable to the worker's present job. Both the nature of the firm's job offers and the specificity of movement and training in the new job option are critical. If job offers are cumulative (i.e., have no time limits), the worker will definitely quit if wages are offered above his present wage plus transfer costs, but he may not do so immediately (nor choose that particular job); instead, he may search further.

If, however, as is frequently the case, the job offer must be accepted or rejected at the time offered, the worker may reject a wage offer above his present wage plus transfer costs, if accepting the new job would seriously restrict future job search. The worker will, in fact, only accept such take-it-or-leave-it wage offers if the offered net wage plus expected future net search returns exceed the present wage plus expected future search returns at the old job, or if

$$(8) \quad W_1 + E(\text{Net Returns to Search} \mid W_1, TC_1) > W_0 + TC_0 + E(\text{Net Returns to Search} \mid W_0, TC_0)$$

The critical factor is TC_1, the new job's transfer costs, which would be a function of geographic isolation from alternative employers, among other factors. If $TC_1 = 0$, no limitations are put on future search and the worker would quit whenever $W_1 > W_0 + TC_0$. If the transfer costs are large, however, so the expected value of future job switch gains are seriously reduced, the worker may pass up a job offer he would otherwise eventually accept. Most jobs require little immediate specific investment by workers; on-the-job training accumulates over time and the worker can usually put off heavy expenditures in moving assets and family to the new location until he has searched to his satisfaction. Therefore, we assume below for simplicity that $TC_1 = 0$, and that a worker will quit immediately if he receives a wage offer greater than his present wage plus transfer costs.

The probability that a worker will quit during a given interval of time will be the probability of receiving a wage offer above the critical wage $W_C = W_0 + TC_0$. This quit probability will depend on the units of search undertaken and the probability of receiving a wage offer above W_C at each search effort. The probability, say p, of receiving a wage offer above W_C in a single drawing from the wage dispersion will be

$$(9) \qquad p = g(v)[1 - F(W_C)]$$

where $g(v)$, again, is the probability of a nonzero wage offer, a positively inclined function of labor demand v, and where $F(W_C)$ is the value of the cumulative dis-

[9] See Gertrude Bancroft and Stuart Garfinkle. In the year 1961, only 15 percent of those who experienced unemployment during the year did so because of a job quit.

tribution function at $W_C = W_0 + TC_0$. Assuming independent trials and that p is constant,[10] a worker who carries out sequential search will have the quit probability set out below,

$$\text{(10)} \quad \text{prob}\{\text{quit}\} = 1 - (1 - p)^N$$

where N is the maximum number of searches the worker will carry out if he is unsuccessful in all attempts (that is, where the unsuccessful searcher's marginal search returns (MR) equal marginal cost (MC)). This follows directly from the fact that $(1-p)^N$ is the probability of *not* quitting in N independent trials since $(1-p)$ is the probability of not quitting in any given trial. Within the period, quits will be distributed according to a geometric lag distribution.

To make the model operational, assume that the total search cost function is quadratic, so $C = bn^2$ with $\partial C/\partial n = 2bn$ where n is the number of searches. In this case, the optimal number of searches N will be,

$$\text{(11)} \quad N = \frac{g(v)}{2b} \int_{W_C}^{\infty} (W_A - W_C) f(W_A) dw_A$$

where all terms have been previously defined. The quit probability, prob $\{\text{quit}\} = 1-(1-p)^N$, behaves in a manner one might expect from the search considerations alone.[11] More job openings, a higher v, will increase the quit probabilities, as will a lower critical wage (whether due to a lower present wage, W_0, or to lower transfer costs, TC) relative to alternative wages. An increased dispersion of alternative wages will also generally increase the quit propensity, although possibly not for extremely low wage workers. The effect of job openings and relative wages will, in fact, be stronger on quit behavior than on search behavior, since these factors affect the likelihood of a quit per unit of search as well as the amount of search. A higher own wage or transfer costs will reduce the quit probability both because the probability of a quit for any amount of search is less and because the economically rational amount of search is less. When aggregated over many individuals, the quit probability equation gives the proportion of employed searchers who are likely to quit in a given cost period. This equation, therefore, is the quit rate model we seek.

Certain simplifications are required, however, before the model can be estimated conveniently. A useful approximation for the quit function can be had by expanding the quit probability function (10), using the binomial theorem,[12] to get

$$\text{(12)} \quad q = \text{prob}\{\text{quit}\} = 1 - (1 - p)^N$$
$$= Np - \frac{N(N-1)}{2} p^2$$
$$+ \text{ higher order terms in } p$$

and then approximating q by dropping the quadratic and higher order terms in p, yielding

$$\text{(13)} \quad q \cong Np$$

But $p = g(v)\phi(W_C)$

where

$$\phi(W_C) \equiv 1 - F(W_C)$$

and

$$N = \frac{g(v)}{2b} [\sigma_A^2 f(W_C) - (W_C - \overline{W}_A)\phi(W_C)]$$
$$= \frac{g(v)}{2b} \phi(W_C)\psi(W_C)$$

where

$$\psi(W_C) = \sigma_A^2 f(W_C)/\phi(W_C) - (W_C - \overline{W}_A)$$

[10] Assuming p constant assumes, in particular, that transfer costs are constant with respect to search.

[11] Formal derivations of the following assertions may be found in an appendix available from the author.

[12] This approach to approximating the theoretical model was suggested by H. Gregg Lewis.

Substituting N and p into (13) gives

$$(14)\qquad q = \frac{[g(v)]^2}{2b}\phi^2\psi = \frac{g(v)^2}{2b}\mu(W_C)$$

where $\mu=\phi^2\psi$. This suggest a partitioning of the quit factors into three parts as the *log* of (14) makes clear,

$$(15)\quad \log q = 2 \log g(v) - \log 2b + \log \mu(W_C)$$

A worker's quit propensity will be an additive function in *logs* of alternative "demand" factors, search cost factors, and wage considerations. Equation (15) will form the core of the quit rate model estimated in the empirical section, although a number of variables, particularly the vacancy rate and the parameters of the alternative wage distribution, are not known with certainty. It is to this second problem that the next section is devoted.

II. Informal Information Flows

The sequential search model developed in the previous section indicates the region of profitable job search with respect to the alternative wage distribution parameters, but the worker in an uncertain world is not given the value of these parameters. The estimation of the wage distribution presumably results from the consideration of informal information flows. The worker is continually receiving bits of information on his wage alternatives from friends and relatives, newspapers, etc., but he faces the problem of how to handle this flow. Is a higher wage paid to a friend a random sampling fluctuation or a sign that wages in other firms are generally higher than the worker's own wage? Presumably enough bits of information indicating others in the same skill class are receiving higher wages (or more precisely, wages that will make search profitable) will convince the worker that his wage is out of line.

An optimal technique which accords well with intuitive notions of how workers handle such information is Abraham Wald's sequential probability ratio test. In the case of a simple hypothesis, the ratio test is a likelihood test in which observations are taken until the ratio of the probability of the sample under the alternative hypothesis to that under the null hypothesis exceeds some constant A (at which point the null hypothesis is rejected) or falls below some constant B (at which point the null hypothesis is accepted). Obviously in this case, a one tail-test is appropriate since the worker is only interested in knowing whether the wage population mean exceeds some value. The constant A and B are functions of the desired significance and power of the test. In setting the power and significance, the worker must consider the tradeoff between the cost of assuming the alternative wages are high enough to justify search when in fact they are not (which will involve uneconomical search) and the cost of assuming the wage is not high enough to justify search when indeed it is (thus foregoing a possible wage improvement, for a time).

As Wald and Wolfowitz have demonstrated,[13] the sequential probability ratio test (which can be simply extended into a generalized Bayesian decision rule)[14] has strong optimal properties. In the case of a simple hypothesis against a simple alternative, this test will minimize expected sample size for given errors whichever hypothesis actually holds. With a normally distributed variate, the average recognition lag of an interesting parameter change is apparently about one-half that of the fixed sample approach. The more the parameter is out of line, of course, the more quickly the change will be discovered (for example, the fewer the observations that will be required to reject the null hypothesis).

[13] See G. Barrie Wetherill, p. 22.
[14] See Thomas Ferguson.

Of particular interest here is the nature of the detection lag. Although Wald demonstrated that under very restrictive assumptions, the distribution of lag time until discovery will be asymptotically normal, generally the distribution will be quite complex and skewed. Two Monte Carlo studies, using normally distributed random variables, found the distribution of discovery times to be approximately lognormal.[15] Since the normal distribution can be approximated discretely by a binomial with equal probability of success and failure, the worker's prediction of his average alternative wage (W_A^P) can be estimated by

$$(16)\quad W_{At}^P = (\overline{W}_{At})^{B_0}(\overline{W}_{At-1})^{B_1}\ldots\cdot(\overline{W}_{At-m})^{Bm}$$

where the B_i are binomial coefficients. Similar lag structures presumably exist for the other unknown variables.

The estimation of the lag structure of (16) is made difficult since both the worker's own wage and his prediction of alternative wages enter the quit function and the two are generally extremely highly correlated. The quit rate function, however, suggests that the difference of the two wage rates is the crucial variable, which means, to a logarithmic approximation, that $ln\ W_0 - ln\ W_A^P = ln\ W_0/W_A^P$ is the appropriate variable, so the two wage rates need not be entered separately.[16] Since the regression requires observable variables, (16) may be introduced to yield

$$(17)\quad \frac{W_{0t}}{W_{At}^P} = \left(\frac{W_{0t}}{\overline{W}_{At}}\right)^{B_0}\left(\frac{W_{0t-1}}{\overline{W}_{At-1}}\right)^{B_1}\ldots\cdot\left(\frac{W_{0t-m}}{\overline{W}_{At-m}}\right)^{B_m}\cdot W_{0t}^{1-B_0}\cdot W_{0t-1}^{-B_1}\ldots W_{0t-m}^{-B_m}$$

The second half of (17), a weighted average of past own wages, is more conveniently estimated in logarithmic first differences, so

$$\begin{aligned}(18)\quad & ln\,(W_{0t}^{1-B_0}\cdot W_{0t-1}^{-B_1}\ldots W_{0t-m}^{-B_m})\\ &= (1-B_0)(ln\ W_{0t} - ln\ W_{0t-1})\\ &+(1-B_0-B_1)(ln\ W_{0t-1}-ln\ W_{0t-2})\\ &+(1-B_0-B_1-B_2)\\ &\cdot(ln\ W_{0t-2}-ln\ W_{0t-3})\\ &+\ldots\end{aligned}$$

Empirically this expectational hypothesis implies that, in the quit rate regressions, the sign of the own wage change coefficients should be negative (since W_0/W_A negatively affects quits) and diminishing in absolute value with time. Intuitively, holding real wage differentials and other demand factors constant, the worker will quit less frequently when wages in general are rising because the worker will see his own wage rising before he discovers other wages have risen as well. This is essentially the Alchian hypothesis.

III. The Quit Rate Regression Model and Results

The basic quit rate model to be estimated here is equation (16),

$$log\ q = 2\ log\ g(v) - log\ 2b + log\ \mu(W_C, \overline{W}_A, \sigma)$$

with the expectational lag structure for alternative wages and other unknown variables specified as in the previous section. This complete quit rate model is estimated (with certain modifications discussed below) using monthly time-series data for twenty-seven disaggregated manufacturing industries over the period January 1959, to December 1968. The twenty-seven industries, while by no means com-

[15] A summary of these is reported in Wetherill, pp. 21–22.

[16] The wage prediction problem is compounded by the fact that, in the real world, future wages are not stationary so the worker must attempt to forecast future wages paid by his own and other firms as well as predict prevailing wages.

prehensive, nevertheless cover a broad range of industry types from heavily concentrated and unionized durable goods industries to highly decentralized consumer goods industries.[17]

The quit rate data and wage rate measures are derived from Bureau of Labor Statistics publications. The all-manufacturing average wage rate was used as a proxy for the mean of the alternative wage distribution ($\overline{W}_A$). For the change in nominal own wage, important in the expectational hypothesis, industry average hourly wages were corrected for changes in overtime pay where possible to give a measure of straight time wage changes.[18]

The vacancy rate data used here are derived from job offers pending with the Bureau of Employment Security, end of month.[19] This measure is economy wide rather than an industry specific job vacancy rate. Although both types of measures would be desirable, only the former is available. This measure should be the more useful of the two in any case since individual surveys indicate most workers do shift industries when they quit. Changes in industry output was included to capture the pure industry labor demand. The interpretation of the output change coefficients, however, is made difficult by auxiliary factors discussed below.

Several other factors suggested by the quit equation as appropriate in the regression analysis lack direct measures and are either ignored or handled in a rather *ad hoc* fashion.[20] In the latter category are job transfer costs, an important element in W_C, the critical wage. Transfer costs will vary both cyclically (when firms become more willing to absorb such costs) and seasonally. The sudden jump in quit rates in late summer, for example, is the result of family heads moving before the school year begins as well as school children quitting work to return to school. An August-September dummy was introduced to capture this effect.

Another major determinant of average worker job transfer costs will be the relative inflow of new workers into the industry. The initial investment a new worker has to make in his job need not be large. Not only can transfer costs be avoided until the worker is sure he wants this particular job, but also the specific human capital arising from "on-the-job training" requires time to accumulate. Time-series seniority data by industry are not available, but relative change in output should be positively correlated with the proportion of workers with little seniority.

The lag structures of relative wages and change in own wage, as suggested by (17) and (18) were estimated in the following ways. The change in own wage rate was entered with a number of lagged values, since the change variables were not highly correlated, and the appropriate number of lagged variables was determined empirically by consideration of experimental regression on three randomly selected industries (336, 365, 324). Similar methods were used with the change in *log* output variables. In each, two lagged monthly values were included. For the relative wage variable, a six period geometric average seemed to fit best in the experimental regressions,

[17] This subset of manufacturing industries was selected because of the availability of monthly output measures independent of employment figures, as reported by Hamermesh.

[18] This correction was possible for all 3-digit industries in the sample but not 4-digit industries since overtime hours are reported only for the more aggregated classifications.

[19] The Bureau of Employment Security figures were kindly supplied to me by J. Peter Mattila. They were compiled by the National Bureau of Economic Research.

[20] In the former category are the alternative wage dispersion and direct search costs. Crude evidence suggests that wage dispersions narrow during prosperity while search costs are likely to fall since firms are more willing to advertise, etc., when the labor market is tight

although the binomially weighted average did no better than the uniformly weighted average so the latter was included in the final regressions. Finally, the vacancy rate lag structure also seemed to fit best with three months of vacancy measures. These were introduced individually and unconstrained although multicollinearity problems cannot be ignored here.

The ultimate functional form for the regression model used to estimate the quit rate function for the twenty-seven industries was the *log* of q in equation (19).

$$q = e^{\alpha_0+\alpha_1 AS} \cdot v^{\alpha_2} \cdot v_{-1}^{\alpha_3} \cdot v_{-2}^{\alpha_4} \tag{19}$$

$$\cdot \left(\frac{W_0}{W_A}\right)_6^{\alpha_5} \cdot \left(\frac{W_0}{W_{0_{-1}}}\right)^{\alpha_6} \cdot \left(\frac{W_{0_{-1}}}{W_{0_{-2}}}\right)^{\alpha_7} \cdot \left(\frac{W_{0_{-2}}}{W_{0_{-3}}}\right)^{\alpha_8}$$

$$\cdot \left(\frac{O}{O_{-1}}\right)^{\alpha_9} \cdot \left(\frac{O_{-1}}{O_{-2}}\right)^{\alpha_{10}} \cdot \left(\frac{O_{-2}}{O_{-3}}\right)^{\alpha_{11}}$$

The results for the individual industries appear in Table 1 for all the variable coefficients except the output variables which are reported in an appendix available from the author upon request. The regressions were corrected for first-order autocorrelation as noted in Table 1 when the null hypothesis of zero autocorrelation was not accepted at the 1 percent level, using the Durbin-Watson statistic.

The vacancy rate coefficients suggest that job openings are a major determinant of month-to-month variation in industrial quit rate performance. At least one of these coefficients is significantly positive at the 0.95 confidence level in twenty-four of twenty-seven industries and normally strongly so, with modal quit rate-vacancy rate elasticities usually in the range 1.0–2.0. The impact of job openings is substantial in the first period in twenty-two of twenty-seven industries with the major vacancy rate impact in the remaining industries occurring in the second month.[21] By the third month, the influence is much weakened and more likely to be perverse in sign. There is a mild, but insignificant, tendency for the modal quit elasticity to be somewhat higher in industries with high average production worker wages.

The six month geometric average of relative wages has a less uniformly strong effect on industry quit rates. The relative wage coefficient is negative in seventeen of twenty-seven industries and significantly negative in nine of twenty-seven. The estimated quit rate elasticities, however, tend to be larger in absolute terms than one when negative, suggesting that wage factors can play a substantial role in some industries. The reasons for the more erratic relative wage results may well be in the limitations of the data. Not only are average production worker wage rates a measure of skill mix as well as wage scales, but the all-manufacturing average production worker wage is perhaps a poor proxy for the mean of alternative wages facing workers in any particular industry.

A result of particular interest is the fact that changes in a worker's own wage, with vacancies and relative wages fixed, has no systematic effect on quit behavior. The coefficients are more likely to be positive than negative and are rarely significant. Apparently workers learn of changes in alternative wage possibilities quickly enough that they are not fooled into believing that their own wages have risen relative to others when wages are rising in general.[22] This evidence casts some doubt on mechanisms proposed for reconciling Phillips curve phenomena in a price theory frame-

[21] Substituting unemployment rates for vacancy rates in the regressions has only minor influence on the results. The unemployment rate coefficients are generally less significant and are more likely to peak in the second or third period.

[22] Replacing changes in own wage with changes in the general price level yields comparably uninteresting results.

work.[23] This bit of evidence, of course, is hardly conclusive. Variable definition and econometric problems make these assertions only tentative. Simultaneity problems, for example, exist here since high quit rates may well lead to wage increases as firms try to hold their workers. Nonetheless, the evidence does suggest that wage "illusion" is not an extremely strong effect.

Turning to the noninformational factors, the August-September dummy has coefficients significantly positive in all industries, documenting the importance of the vacation-school year effect on the workings of the *U.S.* economy. The output change variables (not reported here) have a strong and consistently positive effect on quit rates, presumably because of the direct industry-specific labor demand effect and because of the indirect effect from increasing the proportion of young, quit-prone workers as employment expands. The lag structure of output change is reasonably regular with peak effects in the first or, more likely, second period with quit rate effects in the third period still consequential.

In sum, over the ten-year period 1959–68, the variation in quit rate experiences for a large set of industries can be rather well explained by the variation of a small set of largely search-informational variables. The fluctuation in job openings, industry demand levels, and season of year are particularly strong. Relative wages are somewhat less so, while fluctuations in nominal wage levels generally have no particular relationship to quit rate fluctuations. Perhaps not surprisingly, "real" factors seem to dominate the movement of quit rates.

[23] An anonymous referee points out that the bulk of unemployed are new entrants and laid off workers, not quitters, so the Phillips relationship is not being directly examined. To the extent new entrants and laid off workers receive job condition information at greater cost than do employed workers, this may be an important qualification. Firms themselves may be subject to expectation lags so that vacancy rates will be unrealistically high during periods of unexpected inflation, thereby inducing quits and presumably pushing up wages.

Employment Impacts of Textile Imports and Investment: A Vintage-Capital Model

By PETER ISARD*

"Development can be promoted by aid, but aid cannot and should not be relied on to do the whole job. The low-income countries need . . . improved access for their products to the massive markets of the industrialized nations. Such export increases must come largely in manufactured goods."

President Richard M. Nixon

Although valuable policy guidance continues to emerge from the efforts of development planners to tackle the internal problems of allocating resources within the less developed countries (*LDC*), a strong consensus of opinion maintains that external barriers are among the major obstacles to economic growth. Consequently, there is a need for complementary planning efforts which deal with the problem of shifting production in high-income countries away from the manufactures that are relatively advantageous for *LDC*s to produce for export. This latter problem is loaded with political difficulties, insofar as the large potential markets for *LDC* manufacturing exports also represent the vested interests of large and politically powerful groups within the industrialized nations. Yet there is good reason to conjecture that trade restrictions against *LDC* products would be less severe if politicians were presented with sophisticated economic estimates of the quantities of *LDC* manufactures which industrial countries can import at given short-run costs to their vested interest groups.[1] And as a challenge to the philosophical position of most economists, the time has come to outline quantitative industrial restructuring plans which support the widely preached proposition that trade liberalization can make everybody better off in the long run.

The purpose of this paper is to move toward a plan for limiting or gradually contracting the size of the *U.S.* textile sector, as measured by employment. By focusing on the economic constraints which relate textile employment, imports and investment, it is possible to compute reasonable estimates of the maximum growth of imports that is consistent with any given rate of employment change. The design of efficient policies for achieving desired employment levels, or other domestic textile objectives, can increase the development assistance provided to *LDC*s through *U.S.* textile imports.

It should be noted that there is a considerable difference of opinion on the wisdom of choosing to promote *LDC* exports of textile manufactures. Existing theories and statistical indicators of comparative advantage, both neofactor-proportions and neotechnological accounts, characterize textiles as a manufacture which is strongly favorable to *LDC* production and export.[2] But in a dynamic context, pursuit of high per capita income is an effort to shift

* International Finance Division, Federal Reserve Board. This paper is based upon my unpublished doctoral dissertation and was not influenced by anyone on the Federal Reserve staff. I am particularly grateful for guidance received from Alan S. Manne and Donald B. Keesing.

[1] For example, between 1961 and 1968, *U.S.* restrictions against textile imports not only protected vested interests, but also encouraged a 10.2 percent increase in the number of domestic textile workers. Economic foresight might have promoted a more liberal import policy in order to have avoided this "undesirable" expansion of vested interests.

[2] See Gary Hufbauer.

comparative advantage into activities in which labor productivity is high. Proponents of an outward-looking development strategy stress the importance of attempts to improve the productive and management skills of *LDC* human resources through contact and close competition with the advanced countries.[3] Thus, rather than promoting those exports which are comparatively cheap to produce under initial factor endowments and technological considerations, it is desirable for *LDC*s to engage in those export activities which, through associated learning experiences, are likely to increase most rapidly the productivity of their human resources. From this long-run viewpoint, it is questionable whether strong promotion of *LDC* textile exports is desirable.

From the viewpoint of potential short-run gains, however, the case is more conclusive. Textile and apparel products represent almost 50 percent of the manufactures which *LDC*s have managed to sell to the advanced countries (1965 data),[4] while imports from all sources in 1970 supplied less than 5 percent of the large *U.S.* market for textiles. Consequently, a long range *U.S.* plan to allow the maximum import growth consistent with a gradual contraction of the *U.S.* textile sector could provide sizeable development assistance benefits to the *LDC*s. And under complementary measures designed to neutralize the employment impacts and other potential costs to *U.S.* vested interests, the theory of international trade suggests that the United States as well as the *LDC*s could benefit from such contraction.[5]

[3] See Donald Keesing.

[4] See Hal Lary, Table 16, p. 110.

[5] The international tensions which *U.S.* textile policy has created, both in coercing limitations on exports of noncotton textiles from Japan and other East Asian countries to the United States, and during meetings of the *GATT* Cotton Textiles Committee, provide all the more reason for reconciling in a Pareto-efficient manner the foreign and domestic interests concerned.

This paper takes the following approach to characterizing an efficient *U.S.* textile policy. Section I develops a vintage-capital production model of the *U.S.* textile sector and compares several econometric estimates of the rates of embodied and disembodied technical change. These estimates suggest that the employment impact of a given volume of imports is quite sensitive to the extent of new investment taking place. On the assumption that technical change in labor-output ratios is at least two-thirds embodied, the estimates suggest that employment per unit output with new plant and equipment is between 35 and 49 percent of the unit labor requirement with marginally profitable plant and equipment. It follows that between 51 and 65 percent of the employment impact of imports can be neutralized if a cutback in new plant and equipment investment allows imports to substitute for the additional output of modern mills, rather than the output of marginally profitable mills. Obversely, a cutback in modernizing investment can allow a target employment level to be achieved with more than twice the volume of imports that would be acceptable without the investment cutback.

Section II projects several future time-paths of employment and imports that are jointly feasible under an investment-retirement policy designed to hold approximately constant the estimated age of the oldest operating plant and equipment. This describes several of the "wiser" choices that are available to *U.S.* policy makers. The target retirement age reflects a conjecture on the "maximum practical lifespan" of textile plant and equipment. No doubt, there is a moderate range for error in this conjecture, as well as in the econometric estimates; and in conclusion, Section III discusses the limitations of the analysis. Fortunately, policy can be continually adjusted from year to year in ac-

cordance with the feedback of empirical information; so initial policy formation does not require an extremely high degree of confidence in the estimated implications of each alternative.

I. A Vintage Model of the *U.S.* Textile Sector

The theoretical implications of vintage-capital production models have been developed by Leif Johansen, Robert Solow (1962), and Solow, James Tobin, Christian von Weizsacker, and Menahem Yaari. Subsequently, vintage models have been applied empirically by Richard Attiyeh and James Barr. These models are able: (i) to reconcile fixed capital-labor proportions in existing microeconomic production units with observed capital-labor substitution within industries over time; (ii) to explain the phenomenon of new investment in an industry with idle capacity; and (iii) to distinguish the industry average labor-output ratio from the unit labor coefficient on marginally profitable capital, thereby allowing more accurate estimation of the employment loss which results when imports displace the output of marginally profitable firms.

The following notation is used below.

- t = number of years after 1900
- v = the index of capital vintage of year $1900+v$
- Q_t = aggregate textile production during year t
- L_t = total textile production-worker man-hours employed during year t
- I_v = investment in vintage v plant and equipment, or gross investment during year v
- $I_{v,t}$ = vintage v capital utilized during year t
- $a_{v,t}$ = the labor-output ratio on vintage v capital during year t
- $b_{v,t}$ = the capital-output ratio on vintage v capital during year t
- $m(t)$ = the oldest (marginally profitable) vintage of capital utilized during year t
- d = the physical depreciation rate on capital, per year

It is assumed that:

(i) All investment expenditures during year v are used to purchase plant and equipment of vintage v.

(ii) There is a gestation lag of one year, such that all capital purchased during year v is operable at full capacity during year $v+1$, but cannot operate before year $v+1$.[6]

(iii) Once capital has gestated, it begins to depreciate at a constant exponential rate of d per year.

(iv) During any year in which the level of production falls short of maximum potential output, it is the older capital which stands idle while the more modern plant and equipment produces. More precisely, if any available vintage v capital is left idle during year t, all available vintage $v-1$ capital is also left idle during year t.[7]

Together, assumptions (i)–(iv) define the equations from which the vintage technical parameters can be estimated:

$$(1) \quad I_{v,t} = \begin{cases} 0 & \text{for } t-1<v \\ e^{-d(t-1-v)} I_v & \text{for } m(t)<v\leq t-1 \\ 0 & \text{for } v<m(t) \end{cases}$$

[6] The data restrict attention to annual time periods, with investment data representing gross expenditures on new plant and equipment combined. Hence there are two reasons why a gestation lag of one year seems appropriate. First, investment expenditures, and outlays for new plant in particular, may partly occur before operation can begin. And second, not all plant and equipment is installed on the first day of a given year: most new capacity is only available during a fraction of the year.

[7] This assumption is considerably stronger than it may sound insofar as it requires that whenever any available vintage v equipment is left idle during year t, all available vintage v plant is also left idle. Disaggregated data on plant and equipment investments would make possible a more appealing formulation.

with $0 < I_{m(t),t} \leq e^{-d(t-1-m(t))} I_{m(t)}$

$$(2) \qquad Q_t = \sum_{v=m(t)}^{t-1} \frac{I_{v,t}}{b_{v,t}}$$

$$(3) \qquad L_t = \sum_{v=m(t)}^{t-1} \frac{a_{v,t}}{b_{v,t}} I_{v,t}$$

Technical change is assumed to occur in the form:

$$(4) \qquad a_{v,t} = ae^{-hv}e^{-ct}$$

$$(5) \qquad b_{v,t} = be^{-kv}$$

The unknown parameters h and k represent the rates at which technical change is embodied in successive vintages of capital, while c is the rate of disembodied decline in labor-output ratios over time. There is assumed to be no disembodied change in capital-output ratios.

Equations (1)–(5) reduce to the model:

$$(6) \quad Q_t = \sum_{v=m(t)+1}^{t-1} \frac{e^{kv}}{b} e^{-d(t-1-v)} I_v + \frac{e^{km(t)}}{b} I_{m(t),t}$$

$$(7) \quad L_t = \frac{ae^{-ct}}{b} \left\{ \sum_{v=m(t)+1}^{t-1} e^{(k-h)v} e^{-d(t-1-v)} I_v + e^{(k-h)m(t)} I_{m(t),t} \right\}$$

for some m(t) and $I_{m(t),t}$ such that

$$0 < I_{m(t),t} \leq e^{-d(t-1-v)} I_{m(t)}$$

The Q_t, L_t, and I_v are observed data; while a, b, c, d, h, k, the m(t) and the $I_{m(t),t}$ are the unknowns to be estimated.[8] Production and employment data for the 1943–70 period are presented and discussed in Appendix Table 3. Investment data for 1919–69, together with an explanation of their construction, are available on request from the author.

A weighted first differencing of equation (6) yields:

$$(8) \qquad Q_{t+1} = e^{-d} Q_t + \frac{e^{kt}}{b} I_t + R_t$$

where

$$(9) \quad R_t = \frac{e^{km(t+1)}}{b} I_{m(t+1),t+1} - \frac{e^{-d}e^{km(t)}}{b} I_{m(t),t} + \begin{cases} -e^{-d} \displaystyle\sum_{v=m(t)+1}^{m(t+1)} \frac{e^{kv}}{b} e^{-d(t-1-v)} I_v & \text{if } m(t+1) > m(t) \\ 0 & \text{if } m(t+1) = m(t) \\ + \displaystyle\sum_{v=m(t+1)+1}^{m(t)} \frac{e^{kv}}{b} e^{-d(t-v)} I_v & \text{if } m(t+1) < m(t) \end{cases}$$

The first stage of estimation treats the remainders R_t as approximation errors and uses a non-linear least squares procedure to find that triplet $(\hat{b}, \hat{k}, \hat{d})$ which minimizes the sum of the squared errors:

$$\sum_t \left(Q_{t+1} - e^{-d} Q_t - \frac{e^{kt}}{b} I_t \right)^2$$

The remainder R_t may be viewed as the sum of a "true" approximation error R_t^* plus a stochastic error u_t, where R_t^* is defined from equation (9) under the true parameter values (b^*, k^*, d^*). If the total error terms $R_t^* + u_t$ are independent and

[8] The model can be made more general by replacing (5) with

$$(5') \qquad b_{v,t} = be^{-kv}e^{-ft}$$

where f represents the rate of disembodied decline in capital-output ratios over time. Note then that

$$b_{v,t} = be^{-f}e^{-(f+k)v}e^{-f(t-1-v)}$$

and equation (6) must be replaced by

$$(6') \qquad Q_t = \sum_{v=m(t)+1}^{t-1} \frac{e^{(f+k)v}}{be^{-f}} e^{-(d-f)(t-1-v)} I_v$$

(6′) continued

$$+ \frac{e^{(f+k)m(t)}}{be^{-f}} I_{m(t),t}$$

Thus, estimates of the triplet (b, k, d) under (5) would correspond to estimates of $(be^{-f}, f+k, d-f)$ under (5′).

normally distributed with zero means, then the triplet $(\hat{b}, \hat{k}, \hat{d})$ is the maximum likelihood estimate of (b^*, k^*, d^*).

The validity of assuming that the error terms have zero means is questionable. Under plausible values of (b, k, d), R_t tends to be negative whenever $m(t+1)>m(t)$, tends to be close to zero whenever $m(t+1)=m(t)$, and tends to be positive whenever $m(t+1)<m(t)$. But unless growth of output and investment allow a strong trend of increasing marginal vintage age, the case $m(t+1)>m(t)$ is expected to occur more frequently than the case $m(t+1)<m(t)$. For example, a symmetric distribution of $m(t+1)$ about $m(t)$ with $m(t+1)=m(t)+1$ for 5 out of 20 observation years, $m(t+1)=m(t)$ for 10 years, and $m(t+1)=m(t)-1$ for the remaining 5 years would increase the marginal vintage age by 20 years during the 20-year observation period. Obversely, the marginal vintage age will stay constant only if $m(t)+1$ is the observed mean value of $m(t+1)$. But if $m(t+1)=m(t)+1$ is indeed the expected case, R_t is more likely to be negative than positive. Multiple sampling of the Q_{t+1}, Q_t, and I_t for any particular t would not be likely to yield sample values of $R_t=R_t^*+u_t$ that were normally distributed about a zero mean.

This consideration suggests that the least squares estimates are not unbiased maximum likelihood estimates. To eliminate some of the bias, five cases in which $Q_{t+1}<.98Q_t$ were discarded from the sample; because a large decline in output is likely to induce a decline in marginal vintage age (i.e., $m(t+1)>m(t)+1$), and the associated approximation errors would then be particularly large and negative. Nevertheless, discarding these observations does not guarantee a small bias in the least squares estimates for the remaining observation years.[9]

The least squares estimates for the data period t=49–52, 54, 55, 58, and 60–66 are:[10]

$$(10)\quad (\hat{b}, \hat{k}, \hat{d}) = (.585, .00347, 5.96 \times 10^{-8})$$

While these values cannot be defended well on statistical grounds, on economic grounds they seem quite plausible. The estimate $\hat{d}\approx 0$ says there is virtually no physical depreciation of capital; but rather implies that retirement is attributable almost entirely to technological obsolescence.[11] The estimates $\hat{b}=.585$ and $\hat{k}=.00347$ imply $\hat{b}_v=.585e^{-.00347v}$; so $\hat{b}_{60}=.493$. This may be compared with other data, under the assumption that b_{60} approximates the average capital-output

[9] I am not aware of any formal statistical criterion for judging how seriously these approximation errors will bias the estimates of the non-linear model (8). Attiyeh and Barr have used different estimation procedures. Attiyeh was forced by data limitations to select as his estimates the solution to n equations in n unknowns, a procedure which involves no statistical degrees of freedom. Barr has made use of the assumption that industry average labor compensation represents a uniform competitive wage equal to value-added per worker on the oldest and marginally profitable vintage in operation. Attiyeh's method is clearly undesirable when data are adequate. Barr's method is theoretically elegant; but in fact there are sufficient regional differentials in textile earnings that such a procedure would probably understate marginal vintage age by at least 5 years. Barr's method is also difficult to apply in the open economy context. See Isard (pp. 88–91, 100) for further discussion.

[10] Further stages of estimation make the approximation $\hat{d}=0$.

[11] Throughout the data period, most of the capital estimated to have been in operation was younger than 20 years; and the estimate $\hat{d}\approx 0$ is probably very sensitive to this age structure. Since capital does not last forever, the estimate of negligible depreciation on young capital makes it appealing to use a "one-hoss shay" assumption in the projections of Section II, as will be discussed further below. It may also be noted that the oldest operating age of any vintage during the data period is estimated to have been 32 years (see Table 1 below). However, the shape of the age pyramid suggests that the empirical implications of the model are not very sensitive to the rate of depreciation on capital older than 20 years, and consequently would not be much affected if this rate of depreciation was distinguished and estimated separately from the rate of depreciation on capital younger than 20 years. Finally note that under the generalization outlined in fn. 8, this estimate must be reinterpreted as $\hat{d}-\hat{f}\approx 0$. Physical depreciation is then almost entirely offset by disembodied change in capital-output ratios.

ratio for 1960–61 (or that the weighted-average age of capital in use during 1960–61 was approximately 10 years). There should then be agreement between $\hat{b}_{60}$ and data from *U.S.* corporation income tax returns, which record that the undepreciated book value of textile capital was .415 times textile business receipts in 1960–61.[12] The discrepancy may result in large part from a failure to adjust book values upwards in response to the inflation that has occurred in capital goods prices.

Given the parameters (10), unique values of the m(t) and the $I_{m(t),t}$ can be computed from (6). Table 1 shows the implied ages and birthdates of the marginal vintages in operation during each observation year. The gradual increasing trend in marginal vintage ages can be attributed to an extension of profitable operating lives, due in part to the fact that unit labor requirements fell faster from vintage to vintage than real wages increased from year to year. In addition, rapid demand growth during the 1960's made it profitable for idle mills to resume operations, which also shows up in the marginal vintage age estimates.

As a further test of the estimates, the cyclical behavior of the implied marginal vintage ages may be compared with statistics on unfilled orders, also shown in Table 1. An increase in unfilled orders is expected to draw previously idle vintages back into operation (through cyclical influences on prices and profit rates), thereby increasing the marginal vintage age; and vice versa. This expectation seems confirmed. In only two out of nineteen cases do marginal vintage age and unfilled orders change in opposite directions.

The implied values of the m(t) and the $I_{m(t),t}$ can now be used along with (10) and (1) to compute first the implied $I_{v,t}$ and then that estimate of (a, c, h) which minimizes the sum of the squared errors in (7):

$$\sum_{t=48}^{67}\left(L_t - \frac{ae^{-ct}}{\hat{b}}\sum_{v=m(t)}^{t} e^{(\hat{k}-h)v}I_{v,t}\right)^2$$

The least squares estimate is:

$$(11)\quad (\hat{a}_0, \hat{c}_0, \hat{h}_0) = (1.463, .0403, .0024)$$

The values of $\hat{h}_0$ and $\hat{c}_0$ are rates of change per year; while $\hat{a}_0$ is measured in man-hours per constant (1957–59) dollar's worth of output.

The estimate (11) attributes most of the decline in labor-output ratios to disembodied efficiency increases ($\hat{c}_0 = .0403$), and suggests that very little of the observed change has been embodied in new capital vintages ($\hat{h}_0 = .0024$). This does not conform with a priori expectations. In the

opinion of Solow, purely disembodied change

> does not correspond very well with what actually goes on in the world under the name of technological progress. . . . it is not at all a metaphysical question whether technical progress is predominantly embodied or disembodied; whether gross investment is or is not the major vehicle by which new knowledge makes its way into the process of production. If it is not, then a stationary economy, or even one whose conventionally measured gross investment is zero, will find its productivity increasing as rapidly as a growing economy which allocates a substantial fraction of its capacity to conventionally-measured net investment. If it is, then acts of investment serve the double purpose of adding to the stock of capital goods available for future production and making that stock a little more modern, or raising the average level of technology available for use. [1963, pp. 42–44]

Moreover, such a low rate of embodied change ($\hat{h}_0 = .0024$) implies little difference between unit labor requirements on new and old capital vintages (for example, $\hat{a}_{t-1,t} = .93\ \hat{a}_{t-30,t}$). And with only slight embodied decline in capital-output ratios, it seems difficult to rationalize the observation of high rates of investment in an industry with idle plant and equipment.

For these reasons it was decided to examine how the statistical quality of the estimate would be affected by constraining technical change to be predominantly embodied. Two alternative estimates were computed, corresponding to the hypotheses: (i) that the change in labor-output ratios is purely embodied (i.e., $c=0$); and (ii) that the change in labor-output ratios from one year's newest vintage to the next year's newest vintage, $c+h$, is approximately two-thirds embodied (specifically, $h=.03$). These alternative hypotheses, respectively, yield the least squares estimates

$$(\hat{a}_1, \hat{c}_1, \hat{h}_1) = (.893, 0, .0436) \tag{12}$$

and

$$(\hat{a}_2, \hat{c}_2, \hat{h}_2) = (1.153, .0148, .03) \tag{13}$$

Neither of two statistical comparisons provides more than a very weak basis for choosing between the three estimates (11)–(13).[13]

Because of the difficulty in choosing a preferred estimate, the policy implications of each of the three estimates are presented below. It is nevertheless tempting to assume that technical change is at least two-thirds embodied, in which case the following computations suggest the desirability of policy revision. Under the hypothesis that technical change is approximately

[13] The first comparison computes for each estimate the square root of the mean squared deviation between observed and predicted employments (conventionally called the root mean squared error) as a fraction of the mean observed employment. At the estimates (11), (12), and (13), this statistic takes the respective values .0175, .0603, and .0403. By subtracting these values from unity, measures are obtained of the degree of variance explained by the three estimates. Thus, the estimate (11) explains 98.2 percent, (12) explains 94 percent, and (13) explains 96 percent.

The second comparison tests the accuracy of each estimate in predicting employment levels for 1968–70, the three years following the data period used in estimating the parameters. Each of the estimates consistently underpredicts employment, with predictions becoming progressively worse over time. In part, this may reflect a reluctance of employers to lay off workers during a downturn; and for 1970 it may reflect the additional difficulty of reducing work shifts below 40 hours per week. (Average weekly hours of production workers were 41.2, 40.8 and 39.9 during the three successive years. See U.S. Department of Labor.) On average, the estimate of purely embodied change yields the most accurate predictions, although it is judged the least accurate by the first test above.

	Predicted minus observed employment as a fraction of observed employment		
Year t	Based on (11)	Based on (12)	Based on (13)
68	−.063	−.026	−.059
69	−.074	−.037	−.071
70	−.091	−.100	−.117
Average	−.076	−.054	−.082

two-thirds embodied, the labor-output ratio on the most modern plant and equipment operated during 1970 is estimated to have been 49 percent of the unit labor requirement in the oldest and marginally profitable mills. Similarly, under the hypothesis of purely embodied change, modern mills in 1970 are estimated to have employed 35 percent as much labor per unit output as the oldest operating mills. Therefore, if technical change is at least two-thirds embodied, these estimates suggest that between 51 and 65 percent of the employment impact of 1970 imports could have been neutralized by cutting back 1969 investment in anticipation of the imports, thereby allowing imports to substitute for the additional output of modern mills instead of forcing marginally profitable mills to close. Obversely, such a cut back in new investment would have allowed 1970 imports to increase by an estimated factor between 2.04 $(=1/.49)$ and 2.86 $(=1/.35)$ without affecting 1970 employment.

II. Toward an Efficient Policy for the 1971–85 Period

Under a welfare criterion associated with Pareto, it is widely accepted that no policy should be undertaken unless it is "efficient" in the sense that no other policy could increase the well-being of any one group of economic participants without reducing the well-being of any other group. In practical judgement of economic policy, however, it is difficult to take into account the well-being of all economic participants, or even to define precisely the well-being of those participants who are most affected by the policy in question. Nevertheless, economists generally accept the somewhat vague proposition that it is efficient to expand domestic production of a tradeable good only if the value-added in production is sufficient to pay domestic factors of production their opportunity costs when the product (and each tradeable input) is valued at its world market price.[14]

According to this criterion, it does not seem efficient to encourage the expansion of the *U.S.* textile sector, which requires tariff and quota protection to attract its factors of production. On the other hand, to the extent that existing textile resources are specific to the industry, it is Pareto-efficient to contract domestic textile resources only if vested resources can be compensated for their losses. This suggests that an efficient *U.S.* textile policy is one which liberalizes imports in a manner controlled to phase out the domestic textile sector at the rate at which existing textile capital is scheduled for retirement,[15] and which is accompanied by demand-creation programs to insure a compensating number of new jobs in the regions of import-created unemployment.

Contrary to these considerations, *U.S.* policy encouraged the textile sector to undertake substantial new investment and additions to employment during the 1961–68 period. In 1961, the Kennedy Administration requested that *GATT* meet to seek an "international understanding" on textile trade,[16] which led to the Long Term Arrangement Regarding International Trade in Cotton Textiles (*LTA*).[17] Under the

[14] The "world market price" of a product is not, however, a well-defined concept.

[15] Or can be sold to other countries or converted to other uses without substantial loss to present owners.

[16] This was part of a seven point program of assistance to the *U.S.* textile industry, which represented both a fulfillment of campaign promises and part of a deal in which the textile industry agreed not to lobby against the Trade Expansion Act and the subsequent Kennedy Round negotiations for liberalizing international trade. See Thomas Curtis.

[17] The *LTA*, which became effective on October 1, 1962, after a one-year Short Term Arrangement, relates only to textile and apparel products in which cotton represents more than 50 percent of the fiber content, by weight. Under the terms of agreement, exports of such products may be limited only when they cause "disruptions" in markets of importing countries. According to *GATT*:

These situations [market disruptions] generally con-

LTA, the United States has imposed 5 percent quotas on the annual growth rate of cotton textile imports from most foreign suppliers outside the Western industrial bloc. Introduction of this import protection followed a liberalization of depreciation allowances on textile investments in late 1961, which reduced the average useful tax life of textile mill equipment from 25 to 14 years (and to 12 years for finishing equipment). These measures provided incentives for new textile investments, which were amplified by rapid 5 percent average annual growth of real domestic textile demand during the 1961–68 period. Investment skyrocketed! From annual rates in the range of $300 million constant (1958) dollars during the 1953–61 years, spending on new textile plant and equipment rose steadily to approximately $800 million in 1966, and averaged over $500 million during the 1967–69 years. By mid-1966 this was cause for alarm. To quote Curtis:

> The great increase of productive capacity for the U.S. textile industry is one of the key elements of concern about the future of that industry. The wiser policy would seem to be to unshackle import competition now, through more liberal administration of the long-term arrangement. . . . The real danger is that the capacity being created will only increase pressure to protect this new capacity later even though it be inefficient. It is no favor to the wage earner to entice him into a job which has an unstable economic base. [pp. 20988–89]

By 1968, *U.S.* textile employment had increased to 10.2 percent above its 1961 level, despite more than a 20 percent increase in the average real product of production workers. These new vested interests suffered from the decline in domestic textile demand between 1968 and 1970, which was accompanied by an acceleration of imports of man-made fiber products. As a consequence, the Nixon Administration forced new limitations on textile imports from Japan, Hong Kong, South Korea, and Taiwan.[18] Unless modified in the interest of an efficient long-run textile policy, these new limitations on woolens and man-made fiber products, together with continued use of cotton textile quotas under the *LTA*, are likely to foster a renewed expansion of the domestic textile sector once the *U.S.* economy again begins to exhibit a healthy real growth rate.

Suppose, however, that it is indeed possible to convince political pressure groups of the wisdom of an efficient textile policy. What would constitute an efficient policy for the 1971–85 period?

The answer to this question requires a judgement on the maximum rate at which the *U.S.* textile sector can be contracted without imposing "significant" or "politically unacceptable" costs on existing vested interest groups. This in turn de-

tain the following elements in combination:

(i) a sharp and substantial increase or potential increase of imports of particular products from particular sources;

(ii) these products are offered at prices which are substantially below those prevailing for similar goods of comparable quality in the market of the importing country;

(iii) there is serious damage to domestic producers or threat thereof; . . . .

In connection with sub-paragraph (iii) the "damage" referred to must be damage caused directly by market disruption and not by any change of consumer taste, technological advance, or similar factors. [pp. 14 and 22]

In practice, the United States in particular has interpreted any acceleration of imports as market disruption, even though imports through 1970 have never supplied more than 5 percent of domestic consumption. There have been loud protests from exporting countries, who have twice been forced into renewing the *LTA*, which now extends until October 1973. See Isard, ch. 3.

[18] These limitations cover eighteen categories of textiles and apparels consisting of man-made and wool fibers. Japan has agreed to limit the rate of growth of exports of these products to 5 percent per year, for 3 years; while the other three countries have agreed not to expand their exports by more than 7.5 percent per year, for 5 years. The agreements became effective as of October 1, 1971, with the base year for measurement the 12 months ending March 31, 1971. See *The New York Times*, Oct. 16, 1971, and *The Economist*, Oct. 23, 1971.

pends very much on the potency with which demand-creation programs can be designed to shift workers out of the textile sector into other activities.

For lack of such a judgement, the remainder of this section will consider several alternative rates of contraction of the size of the *U.S.* textile sector, as measured by employment. Under "pessimistic," "preferred," and "optimistic" forecasts of the rate of growth of textile demand, the vintage model and technical change estimates from Section I will be used to compute the growth of imports that is consistent with these alternative rates of employment decline, under an investment-retirement policy designed to hold at approximately 25 years the age of the oldest operating capital vintage. The choice of 25 years as a target retirement age is judged to be approximately optimal insofar as it utilizes existing capital for close to its "maximum practical lifespan" before replacing it with modern plant and equipment.[19]

[19] The estimate (10) suggests that there is almost no physical depreciation on young capital (recall fn. 11), which in turn suggests that once depreciation starts, it proceeds quite rapidly. This makes it tempting to think of capital as a one-hoss shay, which remains as good as new throughout its entire lifespan and then disintegrates instantaneously. If one were to vary the lifespan of the one-hoss shay until its depreciation curve best fit the "true" depreciation curve of textile capital, one would arrive at what I have chosen to call the "maximum practical lifespan" of textile capital. There are several foundations for the conjecture that 25 years approximates this maximum practical lifespan. First, even though Table 1 estimates that vintages as old as 32 years were in operation during the 1961–68 boom, when idle mills were reopened for production, the rise in the ratio of equipment to plant expenditures since World War II suggests a shorter practical lifespan for postwar investments. Second, independent evidence from corporate income tax records for 1954 and 1955, "the latest years in which reported depreciation allowances were largely free from the effects of the adoption of curvilinear depreciation methods under the Internal Revenue Code of 1954," show that depreciation charges by textile firms were consistent with the choice to use physical assets for an average life of 19 years, as opposed to 29 years during the prewar period (see Bert Hickman, pp. 238–43). This provides a lower bound on the maximum practical life.

The base year for projection is 1970, when domestic textile output (Q_{70}), domestic plus export demand (D_{70}), imports (M_{70}) and production-worker employment (L_{70}) were at the levels:

$$Q_{70} = 21.070 \text{ billion constant (1957–59) dollars}$$

$$D_{70} = 22.042 \text{ billion constant (1957–59) dollars}$$

$$M_{70} = 0.972 \text{ billion constant (1957–59) dollars}$$

$$L_{70} = 1.757 \text{ billion production-worker man-hours}$$

Twenty-five capital vintages are estimated to have been in operation to produce Q_{70}, so that average output per vintage was .84 billion. Since the maximum practical lifespan of textile capital has been conjectured to also be 25, it is appealing to consider the simple retirement policy which in each year closes down just enough of the oldest plant and equipment to reduce output capacity (net of new additions to capacity) by .84 billion.[20] When such a retirement policy is combined with new investment at the level I_t, the resulting change in employment between years t and t+1, under full capacity operation, can be approximated as:

$$(14) \quad \begin{aligned} L_{t+1} - L_t = &- .84ae^{-ct}e^{-h(t-25)} \\ &- (L_t - .84ae^{-ct}e^{-h(t-25)})(1 - e^{-c}) \\ &+ \frac{I_t}{be^{-kt}} ae^{-c(t+1)}e^{-ht} \end{aligned}$$

The top line on the right-hand side of this equation represents the employment loss on retired capacity, the second line is the employment loss due to disembodied tech-

[20] It can be computed that during the 1971–85 period such a simple retirement policy would result in the following frequency distribution of marginal vintage ages: 26 years, 3 times; 25 years, 7 times; 24 years, 3 times; 23 years, 2 times.

nical change on all but the most modern vintage, and the third line is the employment gain on new additions to capacity.

Suppose now that $U.S$ policy makers choose to phase out textile employment at the exponential rate z per year, or that the target employment path is

$$(15)\quad L_t = e^{-z(t-70)}L_{70} \quad \text{for } t = 71, \ldots, 85$$

Under the simple retirement policy proposed above, equation (14) defines a stream of investments that will keep textile employment approximately on this target path. In particular, by substituting (15) into (14) and then solving for I_t, this target investment stream is seen to be:

$$(16)\quad I_t = .84be^{25h}e^{-kt} + \frac{b}{a}(e^{c-z} - 1)e^{70z}e^{(c+h+k-z)t}L_{70} \quad \text{for } t = 70, \ldots 84$$

The problems of designing policies or coordination mechanisms to keep new investment (and retirement) on target might in practice prove to be among the more difficult and interesting aspects of an efficient textile policy; but here these problems are by-passed to focus instead upon the question of import liberalization.

If new investment and retirement are kept on target, full capacity output ($\overline{Q}$) of all operable capital follows the time path:

$$(17)\quad \overline{Q}_{t+1} = \overline{Q}_t - .84 + \frac{I_t}{be^{-kt}} \quad \text{for } t = 70, \ldots, 84$$

Adherence to the target employment path requires that domestic production be maintained at these full capacity levels. Thus, if D_{t+1} represents the sum of domestic textile demand plus the demand for $U.S.$ textile exports in year t+1, the level of imports (M_{t+1}) consistent with target employment is

$$M_{t+1} = D_{t+1} - \overline{Q}_{t+1}$$

Alternatively, the increase in imports that is consistent with adherence to target employment is

$$M_{t+1} - M_t = (D_{t+1} - D_t) - (\overline{Q}_{t+1} - \overline{Q}_t)$$

or from (17),

$$(18)\quad M_{t+1} - M_t = D_{t+1} - D_t + .84 - \frac{I_t}{be^{-kt}} \quad \text{for } t = 70, \ldots, 84$$

The growth of demand must be forecast to estimate in advance the increase in imports that is consistent with target employment.

In practice, policy could be designed to announce the rate of import liberalization on a short-term basis, thereby making use of short-term forecasts to predict cyclical movements in demand, and also allowing for adjustments to compensate for errors in previous forecasts of demand growth. Nevertheless, in order to estimate the long-run development assistance implications of any particular target rate of employment decline, and in order to allow exporting countries to forecast the long-run growth of the $U.S.$ market for their products, it is desirable to calculate the import growth that is consistent with long-run forecasts of the growth of demand.

The problems of forecasting the long-run growth of demand have been dealt with in my doctoral dissertation. Exports constitute less than 5 percent of the combined domestic plus export demand, so that the growth rate of domestic demand is a good estimate of the growth rate of the combined demand. Because of the historically erratic nature of domestic demand growth, three alternative forecasts are adopted here. A pessimistic forecast predicts a 2 percent annual exponential rate of growth; a preferred forecast predicts a 3.5 percent rate; and an optimistic forecast predicts 5 percent. The pessimistic rate corresponds roughly to the experience of

the 1950's; and the optimistic rate reflects the 1961–68 experience. The preferred 3.5 percent rate corresponds to a per capita income elasticity of .80 to .83 if real *GNP* grows at 4 percent per year, or .66 to .71 if real *GNP* grows at 4.5 percent, using the range of population projections that are published by the Census Bureau.[21] There is some evidence that *U.S.* industry is basing its future plans on predictions which lie between the preferred and optimistic forecasts.[22]

Under the annual exponential growth rate g, domestic plus export demand in year t is:

$$D_t = e^{g(t-70)} D_{70} \tag{19}$$

and equation (18) becomes

$$M_{t+1} - M_t = (e^g - 1)e^{g(t-70)} D_{70} + .84 - \frac{I_t}{be^{-kt}} \quad \text{for } t = 70, \ldots, 84 \tag{20}$$

Table 2 shows the total growth in imports over the 1971–85 period (i.e., the value of $M_{85}-M_{70}$) that is consistent with target employment under five alternative target rates of employment decline ($z=0$, .015, .03, .045, .06), three alternative forecasts of the rate of demand growth ($g=.02$, .035, .05), the assumption that technical change in capital-output ratios will procede according to the estimate (10), and three alternative hypotheses regarding technical change in labor-output ratios (the parameters of (11)–(13)).

The table suggests that if long-run demand growth slackens from the 5 percent annual pace witnessed during the 1961–68 period, import liberalization is not consistent with a constant (or increasing) level of employment. However, if a target rate of employment decline of at least 3 percent per year is chosen, then the preferred forecast of 3.5 percent annual demand growth allows for substantial growth of imports under any of the three hypotheses regarding technical change in unit labor requirements. It is worth stressing the fact that the import implications are fairly insensitive to the nature of technical change when employment is reduced by at least 3 percent per year. Under the 3 percent target, the preferred demand forecast suggests that imports can increase to more than 11 times their base year level ($M_{70}=.97$) in 1985. Each year would allow imports to increase by an average of at least .67 billion over the previous year's level; and on the average, each year's import total would be at least 5 billion dollars greater than the level of 1970 imports. With preferential trade agreements, if necessary, to insure that a substantial fraction of the additional import orders were captured by the *LDC*s, such a policy would provide a significant amount of development assistance.

III. Qualifications and Conclusions

Several crude assumptions have been adopted in structuring and estimating the vintage model of Section I: the available

[21] If N represents population and g_{DD}, g_N, and g_{GNP} respectively, represent the growth rates of domestic demand, population, and *GNP*, then the per capita income elasticity a is defined implicitly by

$$\frac{DD}{N} = c\left(\frac{GNP}{N}\right)^a$$

where c is a constant; and a is estimated from the implied relationship

$$a = \frac{g_{DD} - g_N}{g_{GNP} - g_N}$$

The Bureau of the Census (1971) forecasts population to grow at an average annual exponential rate between 1.05 percent (the Series E projection) and 1.54 percent (Series B) during the 1970–85 period.

[22] Charles B. McCoy, President of Dupont, the largest man-made fiber producer, has predicted that *U.S.* consumers will increase their purchases of textile products by at least 50 percent between 1970 and 1980 (see *The New York Times*, March 21, 1970). The preferred forecast predicts that demand will increase by 42 percent every 10 years, while the optimistic forecast predicts a 65 percent increase.

[a] In billions of constant (1957–59) dollars.

data did not enable a disaggregation of plant and equipment investment; and the most acceptable method of estimating the model involved the strong error assumption adopted in fitting equation (8). Moreover, the policy alternatives investigated in Section II are based upon a fairly crude conjecture regarding the maximum practical use that can be obtained from textile plant and equipment. Thus, Table 2 is offered as a rough approximation of the maximum import growth that is feasible under alternative target employment paths, for a range of demand growth and technical change contingencies.

Despite the room for empirical refinement, the tenor of the conclusions is strong. With 1970 textile imports representing less than 5 percent of the *U.S.* market, there is substantial room for development assistance through import liberalization. Such development assistance can be made available to *LDC*s through a restructuring of policy toward the long-run goal of gradually phasing out the domestic textile sector. If new investment and capital retirement are controlled in a manner designed to obtain (close to) the maximum practical use from existing plant and equipment, the import levels consistent with any target path of employment decline will be (approximately) maximized. In particular, on the assumption that technical change in labor-output ratios is at least two-thirds embodied, the import levels that are consistent with any decline in textile employment can be increased by an estimated factor of 2.04 to 2.86 if new investment is cut back, in anticipation of the imports, in order to avoid the closure of marginally profitable mills with relatively high unit labor requirements.

Fortunately, policy formulation does not require an extremely high degree of confidence in the estimated economic implications of each alternative. Policy can be adjusted over time as new information becomes available to challenge the wisdom of the target retirement age, the predictions of demand growth, or the accuracy of the estimated capital-output and labor-output ratios. In practice, the major difficulty of designing a policy to phase out comparatively disadvantageous production activities is the strong opposition from groups with vested interests in these activities. The challenge is to construct complementary policies to compensate for the

[a] Billions of production-worker man-hours per year. Constructed using data on production-worker employment and average weekly hours from U.S. Department of Labor.

[b] Billions of constant (1957–59) dollars. Constructed by multiplying the *FRB* production index for textiles (from Board of Governors of the Federal Reserve System) by .1416. This conversion factor was derived using data on value of shipments and end-of-year inventories from Office of Business Economics, *Surv. Curr. Bus.*, various issues, along with a textile consumer price deflator that was provided by the Bureau of Labor Statistics (*BLS*). The deflated sum of value of shipments plus increase in end-of-year inventories (in billions of 1957–59 dollars) was .1416 times as large as the *FRB* index in both 1963 and 1964, and .1417 times as large in 1965.

[c] Billions of constant (1957–59) dollars. Current dollar data are from: Bureau of the Census, *Statistical Abstracts*, various issues; Office of Business Economics, *Surv. Curr. Bus.*, various issues; and U.S. Tariff Commission. The deflator is the *BLS* consumer price index for textiles.

[d] Billions of constant (1957–59) dollars. Domestic demand equals domestic production plus imports minus exports.

losses of these groups, and thus to end their opposition. Without efforts to meet the challenge of restructuring production activities to conform with international comparative advantages, it is pure hypocrisy for politicians in the industrialized countries to express their interest in assisting development by promoting the export of *LDC* manufactures.

A Generalization of the Pure Theory of Public Goods

By Bryan Ellickson*

The concept of a pure public good formalized by Paul Samuelson (1954) has frequently been criticized for failing to admit the possibility of exclusion or crowding. In most public consumption—viewing a movie, belonging to a neighborhood, sending children to school, or sharing a dwelling—one shares consumption with some but not all other members of society. Adding another person to a sharing group while maintaining the quality of the service consumed will in general require additional resources. Most goods are public, but few are purely public.

This paper extends the concept of a public good to cover cases in which exclusion or crowding occurs. Like Samuelson, I assume that a public good is equally available to every member of a group to which it is provided. However, rather than assuming that everyone shares the public good, I permit the partition of the members of the economy into distinct sharing groups or "jurisdictions." The resources required to provide a public good to the members of a jurisdiction may depend on the size of the jurisdiction. Thus, both exclusion and crowding of public goods are admitted into the analysis.

The theory developed here not only permits the analysis of a wide class of public goods but sheds new light on certain results which have been obtained for the case of pure public goods. In particular, when crowding and exclusion are present, the Lindahl equilibrium need not be in the core and the core itself may be empty. These results stem directly from the fact that, within the context of this generalized model of public goods, the aggregate technology set may not be convex.

In contrast to the usual conclusion in economics, the presence of nonconvexity does not prevent further analysis of the allocative process in such an economy. By admitting nonconvexity, the theory is able to accommodate "neighborhood" and "local political jurisdiction" as legitimate analytical constructs. For a fixed assignment of individuals to jurisdictions, it is possible to prove the existence and relative Pareto optimality of a Lindahl equilibrium or of what Duncan Foley (1967) has called a public competitive equilibrium. However, because of the presence of nonconvexity, prices can guide the *assignment* of individuals to jurisdictions only under highly specialized circumstances.

Section I reviews the theory of pure public goods in terms of a three-person economy. Section II introduces crowding of the public good and the possibility of exclusion into this economy and exhibits cases where the Lindahl allocation lies outside of the core and where the core is empty, respectively. Section III explores the nature of the nonconvexity introduced by crowding and exclusion while Section IV interprets this nonconvexity as a type of indivisibility. After a brief discussion in Section V of the type of exclusion assumed in this analysis, Section VI turns to the general question of the relationship be-

* Assistant professor, University of California, Los Angeles. I have benefited greatly from comments by Joseph Newhouse, Joseph Ostroy, and a referee.

tween competitive analysis and the organization of collective consumption—the pattern of sharing public goods. Section VII demonstrates the failure of Lindahl prices to guide the assignment of individuals to jurisdictions. Section VIII relates the theory of public goods developed in this paper to James Buchanan's theory of clubs.

I. Pure Public Goods

Consider a three-person economy with two commodities, one private and one purely public. The tastes of the ith individual are represented by

$$(1) \qquad u_i = x_i g \qquad (i = 1, 2, 3)$$

where x_i is the amount of the private good and g the amount of the public good consumed. The ith individual has an initial endowment, w_i, of the private good; no public goods are initially owned; and public goods cannot be used as inputs to production. The economy faces the resource constraint

$$(2) \qquad cg + \sum_{i=1}^{3} x_i = \sum_{i=1}^{3} w_i$$

where c is a positive constant. The Pareto optimal level of the public good is then[1]

$$(3) \qquad g = \frac{w_1 + w_2 + w_3}{2c}$$

In their search for an analogue to competitive equilibrium in an economy with public goods, economists have given considerable attention to Lindahl equilibria (see Erik Lindahl, Leif Johansen, and Foley (1970)). The distinguishing feature of a Lindahl equilibrium is that taxes are levied in such a manner that each individual's "demand" for the public good will be brought into exact equality with the amount supplied. In our three-person economy, the level of public good supplied in the Lindahl equilibrium is given by equation (3). Setting the price of the private good arbitrarily equal to unity, the budget line of the ith individual will be tangent to his indifference curve at the Lindahl allocation provided that he is taxed an amount[2]

$$(4) \qquad t_i = \frac{w_i}{2} \qquad (i = 1, 2, 3)$$

Foley (1970) has proved under relatively general conditions, satisfied by our three-person economy, that the Lindahl equilibrium exists, that it is Pareto optimal, and that it belongs to the core. Foley puts great stress on the third result: no coalition can, using only its own resources achieve an allocation which makes each of its members better off than in the Lindahl equilibrium. Samuelson (1969) has voiced considerable skepticism concerning the relevance of Lindahl equilibria to the political-economic decision-making process. But as Foley observes: "There is some reason to think that the core is a meaningful political concept" (1970, p. 71).

II. Crowded Public Goods, Lindahl Equilibria and the Core

The case for the relevance of Lindahl equilibria would be stronger if one could prove some analogue of the Scarf-Debreu theorem on the core of a competitive economy. The Lindahl equilibrium would, in the limit, be the only politically relevant allocation. However, a theorem of this type does not seem possible when pure

[1] Equating the sum of marginal rates of substituion to marginal cost, $(x_1+x_2+x_3)/g=c$. Using equation (2), this relation can be translated into equation (3).

[2] To derive the Lindahl taxes, maximize $u_i=x_ig$ subject to the budget constraint $p_g^i g+p_x x_i=p_x w_i$ where p_g^i is the Lindahl price charged to the ith individual and p_x is the price of the private good. From the necessary conditions for a maximum, we obtain $p_g^i g=p_x x_i$. Substituting into the budget constraint yields $x_i=w_i/2$ and $p_g^i g=(p_x w_i)/2$. Letting $p_x\equiv 1$ and $t_i\equiv p_g^i g$ gives the desired result.

public goods are present. If the resource cost of producing a given level of the public good is independent of the number of individuals who consume it, then blocking is very difficult. In looking for ways to enhance the blocking ability of a coalition, it is natural to consider the possibility that the coalition can, by excluding nonmembers, obtain a given level of the public good at lower cost. When the addition of another consumer increases the resources required to maintain the level of public good consumed by all, we will refer to the public good as "crowded."

We will now introduce crowding into our three-person economy. If all three individuals consume the public good jointly, then we assume, as before, that they face the resource constraint given by equation (2). However, an individual who decides to produce the good g using only his own resources faces the constraint

$$ag_i + x_i = w_i \qquad (i = 1, 2, 3) \tag{5}$$

where a is a positive constant.[3] Any pair of individuals i and j $(i \neq j)$ face the constraint

$$bg_{ij} + x_i + x_j = w_i + w_j \tag{6}$$

provided that they share consumption of the public good.[4]

To be in the core, a vector of utilities (u_1, u_2, u_3) must be *individually rational*; i.e., every individual must obtain at least as much utility as he could using only his own resources. In our three-person economy, (u_1, u_2, u_3) is individually rational if, and only if,[5]

$$u_1 \geqq \frac{(w_1)^2}{4a} \equiv v(\bar{1}); \quad u_2 \geqq \frac{(w_2)^2}{4a} \equiv v(\bar{2}); \quad u_3 \geqq \frac{(w_3)^2}{4a} \equiv v(\bar{3}) \tag{7}$$

Although a pair of individuals forming a blocking coalition may choose to consume the good g privately rather than sharing it, we will, in order to simplify the exposition, assume that g is a pure public good for coalitions of size less than or equal to two; i.e., $a=b$. In that case, the set of utilities that a pair of individuals can obtain through private consumption of the "public" good is a proper subset of the set of utilities obtainable through joint consumption. Under these circumstances, equation (6) is the appropriate resource constraint for a two-person blocking coalition.

If (u_1, u_2, u_3) is to be in the core, then it must not be possible for any two-person coalition, using only its own resources, to obtain higher utility levels for both of its members. Therefore, (u_1, u_2, u_3) is in the core only if[6]

$$\begin{aligned} u_1 + u_2 &\geqq \frac{(w_1 + w_2)^2}{4b} \equiv v(\overline{12}) \\ u_1 + u_3 &\geqq \frac{(w_1 + w_3)^2}{4b} \equiv v(\overline{13}) \\ u_2 + u_3 &\geqq \frac{(w_2 + w_3)^2}{4b} \equiv v(\overline{23}) \end{aligned} \tag{8}$$

Returning to the case where all three individuals consume the public good jointly,[7]

[3] If the public good is uncrowded (i.e., if it is a pure public good) then $a=c$.

[4] If they consume the good g privately, then the resource constraint would be $a(g_i+g_j)+x_i+x_j=w_i+w_j$. To avoid an unnecessary complication, we will rule this possibility out by assumption.

[5] These expressions, as well as those of (8) and (9) below, are derived by determining the Pareto optimal "utility frontier" for each coalition using its resources alone and the resource constraint appropriate to its size.

[6] See fn. 5. In this case, the utility frontiers happen to be linear, but that will not be true in general even for three-person two commodity economies of the sort we are discussing. The counter-examples of this section can be obtained in the more general case, but the exposition would be unnecessarily complicated.

[7] We should consider other possible "partitions": e.g., 1 and 2 consuming jointly and 3 privately. But we rule out these other partitions by assuming that all individually rational utility vectors achievable under such a partition form a proper subset of the utility vectors determined by $u_1+u_2+u_3 \leqq v(\overline{123})$. One can show that

Pareto optimal utility vectors satisfy the equation

$$(9)\quad u_1 + u_2 + u_3 = \frac{(w_1 + w_2 + w_3)^2}{4c} \equiv v(\overline{123})$$

The inequalities (7) and (8) and equation (9) describe a type of game that is particularly easy to analyze: a game with transferable utility.[8] For any coalition S, the number $v(S)$ represents the minimum utility the coalition must receive if it is not to block. The number $v(S)$, defined over all possible coalitions, is called the characteristic function of the game.[9]

This game will have a nonempty core if, and only if,[10]

$$(10)\quad v(\overline{12}) + v(\overline{13}) + v(\overline{23}) \leqq 2v(\overline{123})$$

If (10) is satisfied, the game is said to be *balanced*.[11] Substituting (8) and (9) into (10), we obtain

$$(11)\qquad \frac{c}{b} \leqq \frac{k_1 + 2k_2}{k_1 + k_2}$$

as the necessary and sufficient condition for a nonempty core where $k_1 = (w_1)^2 + (w_2)^2 + (w_3)^2$ and $k_2 = w_1w_2 + w_1w_3 + w_2w_3$.

Having completed these preliminaries, we can now demonstrate the two propositions mentioned in the introduction: the Lindahl equilibrium is not necessarily in the core, and the core may be empty.

To establish the first proposition, let $a = b = 1$, $c = 4/3$, $w_1 = w_2 = 2$ and $w_3 = 1$. Substituting these values into (7), (8), and (9) we obtain the following game:

$$(12)\quad v(\overline{1}) = 1; \quad v(\overline{2}) = 1; \quad v(\overline{3}) = 1/4$$
$$v(\overline{12}) = 4; \quad v(\overline{13}) = 9/4; \quad v(\overline{23}) = 9/4$$
$$v(\overline{123}) = 75/16$$

From (11), the game will be balanced if $c \leqq 25/17$; since $c = 4/3$, the game has a nonempty core. A utility vector in the core must satisfy the inequality $u_1 + u_2 \geqq v(\overline{12}) = 4$, so the third individual can receive at most $v(\overline{123}) - 4 = 11/16$; individual rationality requires that he receive at least $v(\overline{3}) = 1/4$. Thus, for all utility vectors in the core, $1/4 \leqq u_3 \leqq 11/16$. (2, 2, 11/16) and (2, 39/16, 1/4) are, for example, two utility vectors that are in the core.

We have already observed that, in the Lindahl equilibrium,[12] $g = (w_1 + w_2 + w_3)/2c$ and $x_i = w_i/2$; consequently,

$$(13)\quad \bar{u}_i = \frac{w_i(w_1 + w_2 + w_3)}{4c} \qquad (i = 1, 2, 3)$$

For the particular parameter values we have selected, the Lindahl utility vector is $(\bar{u}_1, \bar{u}_2, \bar{u}_3) = (15/8, 15/8, 15/16)$. Since $\bar{u}_1 + \bar{u}_2 + \bar{u}_3 = 75/16$, the Lindahl equilibrium is a Pareto optimum. But individuals 1 and 2, who can obtain $(u_1, u_2) = (2, 2)$ using only their own resources, will block this Lindahl allocation. The Lindahl equilibrium fails to give sufficient recognition to the "power" of individuals 1 and 2—they receive too little and individual 3 receives too much—and, hence, the Lindahl allocation is not in the core. However, individual 3 is willing to allow individuals 1 and 2 to receive more than their "Lindahl share" if they share consumption of the public good with him: there are allocations involving joint consumption by all three individuals that are in the core.[13]

this condition will be satisfied if, and only if, the game as represented by (7), (8), and (9) is superadditive. In all of the examples to be presented, this superadditivity condition will be satisfied.

[8] As noted previously, utility is transferable only because the utility frontiers happen to be linear in the particular example.

[9] $v(S)$ is also the best that S can do assuming that $\overline{S}$ does its worst—the usual definition of the characteristic function.

[10] See L. S. Shapley. Strictly speaking, this condition will be sufficient only if the game is superadditive. This additional condition is satisfied in all of the examples to be discussed.

[11] For a discussion of balance in an economic context, see Herbert Scarf.

[12] See equation (3) and fn. 2.

[13] In fact, all allocations in the core involve sharing among all three individuals in this example.

We summarize this result in the following proposition:

PROPOSITION 1: *If public goods are crowded, then the Lindahl equilibrium may not be in the core.*

The second proposition that we wish to establish is that the core can be empty if public goods are crowded.[14] Letting $a=b=1$ and $w_1=w_2=w_3$ the balance condition (11) states that the core will be empty if $c>3/2$. If $c=3/2$ is interpreted as "constant returns to scale" in moving from two- to three-person sharing groups, then we find that the core is empty when there are diminishing returns to scale. One should not conclude, however, that the core will necessarily be nonempty whenever returns to scale are constant or increasing. For example, when $w_1=w_2=4$, $w_3=3$, $a=b=1$, and $c=3/2$, the core is empty.[15] In summary, we have demonstrated:

PROPOSITION 2: *If public goods are crowded, the core may be empty.*

III. Nonconvexity

To what can these rather surprising results be attributed? They stem from an assumption, implicit in the preceding section, that the aggregate technology set is nonconvex. Making this assumption explicit will be greatly facilitated if we formalize our approach to crowded public goods along the lines of Foley (1970).

We assume that the economy has one public good, m private goods, and n consumers. An *allocation* is a vector $(g_1, \ldots, g_n; x_1, \ldots, x_n)$ with each x_i itself a vector in E^m, such that for all i there is a $(g_i; \bar{x}_i)$ with $\bar{x}_i<x_i$ belonging to the consumption set of the ith consumer.[16] An allocation is *feasible* if $(g_1, \ldots, g_n; z)\in Y$ where Y is the aggregate technology set, w_i is the ith individual's initial endowment of private goods,[17] and $z=\sum_{i=1}^{n}(x_i-w_i)$ is the aggregate input of private goods into public good production. Of the assumptions which Foley makes about the aggregate technology set, the one which we will find inappropriate in an economy with crowded public goods is that Y is a convex cone.[18]

DEFINITION: A *Lindahl equilibrium* with respect to $w=(w_1, \ldots, w_n)$ is a feasible allocation $(g_1, \ldots, g_n; x_1, \ldots, x_n)$ and a price system $(p_g^1, \ldots, p_g^n; p_x)\geq 0$ such that

$$\text{(a)}\quad \sum_{i=1}^{n} p_g^i g_i + p_x\cdot z \geqq \sum_{i=1}^{n} p_g^i \bar{g}_i + p_x\cdot\bar{z} \quad \text{for all } (\bar{g}_1, \ldots, \bar{g}_n; \bar{z}) \in Y;$$

$$\text{(b)}\quad \text{if } (\bar{g}_i; \bar{x}_i)\succ_i (g_i; x_i) \text{ then } p_g^i\bar{g}_i + p_x\cdot\bar{x}_i > p_g^i g_i + p_x\cdot x_i = p_x\cdot w_i$$

Observe that there is a separate public good price, p_g^i, for each individual. In the

[14] This proposition runs counter to a theorem of Shapley and Martin Shubik that when external economies are present but external diseconomies are not then the core is always nonempty provided that utility and production functions satisfy the sufficient conditions for the existence of a competitive equilibrium. However, as we will see in the following section, the *aggregate* technology set will be nonconvex in this example. Results similar to Proposition 2 have been obtained by Shubik and by Joseph Ostroy.

[15] The reader can verify that this game is superadditive so that (9) is the appropriate characteristic function for $v(\overline{123})$.

[16] The assumptions on the individual consumption sets and preference orderings introduced by Foley, which are quite standard, will be adopted in this study. Each consumer chooses a point $(g_i; x_i)$ in a consumption set X_i on which there is defined a complete and transitive ordering $>_i$. The individual consumption sets are closed and convex and have an interior in the private good subspace. If $(g_i; x_i)\in X_i$, then there is a point $(g_i; \hat{x}_i)\in X_i$ with $\hat{x}_i<w_i$. The aggregate consumption set, $X=\Sigma_{i=1}^{n} X_i$, has a lower bound for $\leq$. The individual preference orderings satisfy assumptions of continuity, convexity, and monotonicity.

[17] No public goods are initially owned.

[18] We will adopt the other assumptions on Y introduced by Foley: Y is closed, $0\in Y$ (inaction is possible), no production other than inaction is possible without input of some private good, it is possible to produce the public good and the public good is unnecessary as a productive input.

Lindahl equilibrium, producers maximize profits and consumers maximize utility taking prices as given. Foley's definition of a Lindahl equilibrium is restricted to the special case of a pure public good where $g_1 = \ldots = g_n$. However, the concept of a Lindahl equilibrium, as defined above, can be applied to any pattern of sharing.

At this point, it is useful to formalize the notion of alternative patterns of sharing of the public good. Let $N \equiv \{1, \ldots, n\}$ denote the index set of consumers in the economy. Any subset of N representing a group of consumers who share consumption of the public good will be called a *jurisdiction*; the jth jurisdiction will be denoted J_j. Assume that every consumer belongs to exactly one jurisdiction. A particular assignment of consumers to jurisdictions, $\{J_1, \ldots, J_r\} \equiv P_k$, is a *partition* if

$$\bigcup_{j=1}^{r} J_j = N$$

The collection of possible partitions will be denoted by $\mathcal{P} = \{P_1, \ldots, P_s\}$. We reserve P_1 for the *private good partition* $(P_1 = \{\{1\}, \ldots, \{n\}\})$ and P_s for the *pure public good partition* $(P_s = \{N\})$. To any partition P_k corresponds an aggregate technology set $Y(P_k)$. In Foley's model of pure public goods, $Y = Y(P_s)$; in the standard model of private goods, $Y = Y(P_1)$.

Consider the three-person economy described in Section II. We assumed that the ith individual using only his own resources to produce the good g faced the resource constraint $ag_i + x_i = w_i (i = 1, 2, 3)$. Therefore, the production sets for the three consumers are the halflines[19] respectively associated with the vectors

$$\overset{1}{y}_1 = (1, 0, 0; -a) \tag{14}$$

$$\overset{1}{y}_2 = (0, 1, 0; -a)$$

$$\overset{1}{y}_3 = (0, 0, 1; -a)$$

where the vectors are written in the form $(g_1, g_2, g_3; z)$ with z representing the input, $x_i - w_i$, of private goods into the production of the public good. We also assumed that a pair of individuals $\overline{ij}$, using their own resources and sharing consumption of the public good, faced the constraint $bg_{ij} + x_i + x_j = w_i + w_j$. The production sets for the pairs $\overline{12}$, $\overline{13}$, and $\overline{23}$ are the halflines respectively associated with the vectors

$$\overset{2}{y}_1 = (1, 1, 0; -b) \tag{15}$$

$$\overset{2}{y}_2 = (1, 0, 1; -b)$$

$$\overset{2}{y}_3 = (0, 1, 1; -b)$$

Finally, we assumed that the constraint facing the three consumers if they consume the public good jointly is $cg + x_1 + x_2 + x_3 = w_1 + w_2 + w_3$; the production set is then the halfline associated with the vector

$$\overset{3}{y}_1 = (1, 1, 1; -c) \tag{16}$$

If we assume that, for a given partition P_k, the economy as a whole has the same technological capacity for producing goods for a component jurisdiction that the jurisdiction has when operating in isolation, then the aggregate technology set $Y(P_k)$ for the partition P_k is a convex cone.[20] In Section II, the partition P_k was

[19] The halfline (b) associated with the vector b is the set $\{x \mid x = \lambda b, \lambda \geqq 0\}$.

[20] Specifically,

$$Y(P_1) = \{y_i \mid y_i = \alpha \overset{1}{y}_1 + \beta \overset{1}{y}_2 + \gamma \overset{1}{y}_3, \alpha, \beta, \gamma \geqq 0\}$$

for the partition $P_1 = \{\{1\}, \{2\}, \{3\}\}$ which implies the constraint

$$a(g_1 + g_2 + g_3) + x_1 + x_2 + x_3 = w_1 + w_2 + w_3;$$

$$Y(P_2) = \{y_i \mid y_i = \alpha \overset{2}{y}_1 + \beta \overset{1}{y}_3, \alpha, \beta \geqq 0\}$$

for the partition $P_2 = \{\{12\} \ \{3\}\}$ which implies the constraint

$$b(g_{12}) + ag_3 + x_1 + x_2 + x_3 = w_1 + w_2 + w_3;$$

not assumed to be given; the aggregate technology set implicit in that analysis admitted the use of production technologies corresponding to any of the possible partitions. Suppose we assume that the aggregate technology set is the convex cone generated by the halflines associated with the coalition production vectors (14), (15), and (16); i.e.,

$$(17)\quad Y = \sum_{i=1}^{3} (\overset{1}{y_i}) + \sum_{i=1}^{3} (\overset{2}{y_i}) + (\overset{3}{y_1})$$
$$= conv\left(\bigcup_{k=1}^{5} Y(P_k) \right)$$

where (y_i^j) is the halfline associated with y_i^j and *conv* denotes the convex hull. Since Y is a convex cone and we have adopted Foley's other assumptions on the aggregate technology set, individual consumption sets and individual preference orderings, the Lindahl equilibrium (as defined above) will exist, it will be Pareto optimal, it will be in the core and, hence, the core will necessarily be nonempty.[21] But in Section II we produced examples where the Lindahl equilibrium was not in the core and where the core was empty. What is the reason for this contradiction?

To find the source of contradiction, consider our three-person economy with $a=b=1$, $c=3/2$, $w_1=w_2=2$, and $w_3=1$. We will first calculate explicitly the Lindahl equilibrium for this case. Observe that every allocation in Y lies within the convex cone generated by the halflines associated with the production vectors for two-person sharing;[22] i.e., $(y_1^2)+(y_2^2)+(y_3^2)$. This implies that the economy faces the resource constraint

$$(18)\quad (g_1 + g_2 + g_3)/2 + x_1 + x_2 + x_3 = w_1 + w_2 + w_3$$

Given the constraint (18), part (a) of the definition of a Lindahl equilibrium implies that $p_g^1 = p_g^2 = p_g^3$.[23] If $p_x = 1$, then $p_g^i = 1/2$ for $i=1, 2, 3$; the Lindahl allocation is $(g_1, g_2, g_3; z) = (2, 2, 1; -5/2)$ and the corresponding utility vector is $(u_1, u_2, u_3) = (2, 2, 1/2)$.[24] Using the values of the characteristic function given in (12), it is easily verified that this Lindahl equilibrium is in the core.[25]

However, if we follow the approach described in Section II, we find that the only utility vector in the core is (2, 2, 1/4) corresponding to the partition $\{\{12\}, \{3\}\}$.[26] To isolate the source of contradic-

---

$$Y(P_3) = \{y_i \mid y_i = \alpha \overset{2}{y_2} + \beta \overset{1}{y_2}, \alpha, \beta \geqq 0\}$$

for the partition $P_3 = \{\{13\}, \{2\}\}$ which imples the constraint

$$b(g_{13}) + ag_1 + x_1 + x_2 + x_3 = w_1 + w_2 + w_3;$$

$$Y(P_4) = \{y_i \mid y_i = \alpha \overset{2}{y_3} + \beta \overset{1}{y_1}, \alpha, \beta \geqq 0\}$$

for the partition $P_4 = \{\{23\}, \{1\}\}$ which implies the constraint

$$b(g_{23}) + ag_1 + x_1 + x_2 + x_3 = w_1 + w_2 + w_3; \text{ and}$$

$$Y(P_5) = \{y_i \mid y_i = \alpha \overset{3}{y_1}, \alpha \geqq 0\}$$

for the partition $P_5 = \{\{123\}\}$ which implies the constraint

$$cg + x_1 + x_2 + x_3 = w_1 + w_2 + w_3.$$

[21] The proofs in Foley (1970) are easily extended; to conserve on the length of this article, they are left to the reader.

[22] Provided that at least two of the three individuals consume positive amounts of the public good. The assumptions in our example rule out corner solutions where some individuals consume none of the public good. Observe that when $g_1 = g_2 = g_3$, the constraint (18) is the same as the constraint faced when the technology vector for three-person sharing, y_1^3, is used.

[23] Assuming that every individual consumes a positive amount of the public good.

[24] p_g^i = marginal cost = $\frac{1}{2}$. From the demand side, $p_g^i g_i = p_x x_i = x_i = w_i/2$ if $p_x = 1$ (see fn. 2) so $(g_1, g_2, g_3) = (2, 2, 1)$ and $z = -(w_1+w_2+w_3)/2 = -5/2$.

[25] The value for $v(\overline{123})$ is no longer correct since c now equals 3/2.

[26] If consumption of the public good is shared by all three individuals, then $v(\overline{123}) = 25/6$. Using this value in place of the value used for $v(\overline{123})$ in (12), we find that the game described is no longer superadditive. As discussed in fn. 7, this nonsuperadditivity implies that equation (9) no longer represents the entire set of individually rational and Pareto optimal allocations for the coalition of the whole. In particular, the sole core allocation is obtained via the partition $\{\{12\}, \{3\}\}$ for which the Pareto optimal utility frontier is given by

$$(u_1 + u_2)^{1/2} + (u_3)^{1/2} = 5/2$$

tion, examine the pattern of sharing used to attain the Lindahl allocation:

$$(19)\quad (2, 2, 1; -5/2) = (3/2)y_1^2 + (1/2)y_2^2 + (1/2)y_3^2$$

This is not a partition, but rather a set of *overlapping jurisdictions*: individuals 1 and 2 consume 3/2 units of the public good through mutual sharing which each supplements by sharing an additional 1/2 unit with individual 3. But in Section II we ruled out any pattern of sharing that assigned an individual to more than one jurisdiction; only partitions were regarded as admissible. Although the aggregate technology set admits any production vector that belongs to the union of the partition technology sets, linear combinations of these vectors will be feasible only if the jurisdictions form a partition. As a consequence, the aggregate technology set is nonconvex:

$$Y = \bigcup_{P_k \in \mathcal{P}} Y(P_k) \neq conv \bigcup_{P_k \in \mathcal{P}} Y(P_k)$$

IV. Indivisibility

The basis for this nonconvexity is, in a fundamental sense, an indivisibility—an indivisibility not of plants or commodities but of individuals. In assigning consumers to "neighborhoods," for example, we rule out the possibility of fractional assignments; a person cannot be two places at the same time. Referring to our numerical example, individuals 1 and 2 will not, for they cannot, receive two units of the public good by combining 3/2 units from their own two-person neighborhood with 1/2 unit received from two-person neighborhoods formed with individual 3. If 1 and 2 admit individual 3 as a neighbor, then a three-person neighborhood is formed, not a set of three overlapping two-person neighborhoods. But in moving from a two to a three-person neighborhood, the resources required to maintain the same "neighborhood quality" (g) increase by 50 percent. If individual 3 were as wealthy as 1 or 2, then a three-person neighborhood would be formed and the core allocation would give two units of the public good to everyone. However, individual 3 is not as wealthy as 1 or 2, and the best that a three-person neighborhood has to offer is 5/3 units of the public good.[27] Thus, two separate neighborhoods are formed: a high income neighborhood for 1 and 2 and a low income neighborhood for 3. And that outcome, drawing upon casual observation, seems a reasonable picture of what would in fact happen.

The impossibility of assigning fractions of individuals to jurisdictions is characteristic not only of neighborhoods but local public goods in general. We do not observe consumers belonging to more than one school district: the school services from several districts cannot be added to yield greater benefit. Interjurisdictional spillovers may present an opportunity for fractional membership in some sense, but there is certainly no reason to think that such spillovers will in general lead to convexity of the aggregate technology set. Although further elaboration of the model to incorporate spillovers may be worthwhile, the formulation as it now stands is rich enough to cover a number of interesting cases. Prohibiting overlapping memberships in jurisdictions has one distinct advantage—the barriers to convexity of the aggregate technology set in the presence of crowded public goods are thrown into bold relief.

Finally, one can view a household, jointly consuming a house or car, as a jurisdiction in our sense. We have, by assumption, ruled out membership in more than one household for any given in-

[27] Use equation (3).

dividual. In assessing the reasonableness of this assumption, it is important to remember that we have confined our discussion to economies having a *single* public good. We do not rule out membership in other jurisdictions—a poker group for the husband, a bridge club for the wife— if *other* public goods are involved.

V. Excludability

Implicit in our treatment of public goods is an assumption concerning the ability to exclude which should be made more explicit. Richard Musgrave, in particular, puts great stress on nonexcludability in consumption as a characteristic of public goods that is quite distinct from "nonrivalness" in consumption (or what I have called the absence of crowding).

Musgrave concludes that the presence or absence of crowding and the presence or absence of the ability to exclude gives rise to four different types of public good (see pp. 126–29). However, of the four possible cases, three have precisely the same core: the two cases of crowded and uncrowded public goods where exclusion is impossible and the uncrowded case with exclusion. If exclusion is impossible, then a blocking coalition S must assume that the members of the complementary coalition $\overline{S}$ will share the benefits of any public good produced by S; the set of utility vectors that S can obtain using only its own resources, $v(S)$, is the same whether the public good is crowded or not. The set of utility vectors that could be obtained if the members of $\overline{S}$ could be excluded from consumption is irrelevant when exclusion is impossible. If exclusion is possible but the public good is uncrowded, then $v(S)$ is the same as in the two cases just discussed: if exclusion of the members of $\overline{S}$ does not reduce the resource requirements for producing the public good for S, then whether $\overline{S}$ is excluded or not has no impact on the utility vectors achievable by S using only its own resources.[28]

The remaining case to be considered, where exclusion is possible and the public good is crowded, is the one most relevant to the analysis presented in this paper.[29] The core will be smaller than in the three preceding cases. Because exclusion reduces crowding, the blocking possibilities of any coalition S are enhanced. In our earlier discussion, exclusion has been assumed implicitly to be both *complete*[30] and *costless*, but incorporation of partial or costly exclusion into the analysis does not appear to raise any particular difficulties.

Thus, from the point of view of the analysis of allocations in the core, the four cases we have been discussing reduce to just two: the *pure public good* case (broadly defined to include the absence of the ability to exclude, the absence of crowding or both) and the *crowded public good* case with *exclusion*. Foley's model can be applied directly to the first case; the approach developed in this paper is directed to the second. In our model jurisdictions are permitted to exclude, but there is no exclusion within jurisdictions.[31] Within this analytical framework, the distinction between exclusion and crowding is inessential. Both concepts are incorporated into the definition of the aggregate technology set.

[28] However, in this case the ability to exclude may still be relevant to the bargaining process. The characteristic functions, as we have defined them, assume that the complementary coalition will "do its worst": $\overline{S}$ is assumed to provide no public good, or, if it does, to exclude S. This approach essentially rules out the "free rider" problem. Introducing "more realistic" assumptions about the complementary coalition's behavior would increase the number of allocations that can be blocked and decrease the size of core. For a related discussion, see R. W. Rosenthal.

[29] It is instructive to work through all four cases in terms of the example presented in Sections II and III.

[30] In other words, S can exclude $\overline{S}$ from all benefits of the public good produced by S.

[31] The absence of internal exclusion is essentially the defining characteristic of a jurisdiction.

VI. Prices and the Organization of Collective Consumption

I have argued that a reasonable theory of crowded public goods must recognize the nonconvexity of the aggregate technology set. Only in this way can the theory permit the existence of distinct sharing groups: neighborhoods, local political jurisdictions, clubs, and households. But in relinquishing convexity, have we given up too much? If most consumption involves sharing to some extent—within the household if nowhere else—and if nonconvexity vitiates competitive equilibrium analysis, then we are forced to conclude that the main body of economic theory has almost no relevance to the way resources are allocated.

The situation we face is remarkably parallel to that addressed by Samuelson as he neared the end of his paper on social indifference curves:

> Now I have proved the impossibility of group or community preference curves. But haven't I in a sense proved too much. Who after all is the consumer in the theory of consumer's (not consumers') behavior. Is he a bachelor? A spinster? . . In most of the cultures actually studied by modern economists the fundamental unit on the demand side is clearly the "family," and this consists of a single individual in but a fraction of the total cases.
>
> [1956, pp. 8–9]

Samuelson recognizes explicitly that family decision making raises issues "exactly of the same logical character" (1956, p. 10) as the theory of public expenditure, but his reconciliation between family decision making and standard demand analysis is limited to the special case where each family member consumes privately and the family as a whole maximizes its social welfare function. However, it is crucial for our purposes to face squarely the public character of family consumption. Fortunately, a reconciliation between "public" consumption within families and standard competitive analysis is possible—without the contrivance of a family welfare function.

Expecting the tools of competitive equilibrium analysis to explain the pattern of sharing that will emerge in an economy is clearly asking too much. General equilibrium analysis has never tried to explain household formation—or the formation of firms, for that matter. The organization of the economy, the set of consuming and producing agents, has always been regarded as given. Competitive analysis explains the economic activity (consumption and production) of these agents, not their existence.

Therefore, we might expect that competitive analysis, or some variant of competitive analysis, could be applied to an economy with public goods when the partition, the pattern of sharing, is predetermined. And that, in fact, is precisely the case. If the partition P_k is given, the assumption that $Y(P_k)$ is a convex cone is no less (and no more) reasonable than the corresponding assumption for a pure private good economy. Along with the other assumptions concerning preferences and production used by Foley, the assumption that $Y(P_k)$ is a convex cone is sufficient to guarantee the existence, Pareto optimality and inclusion in the core of the Lindahl equilibrium as we have defined it.[32] Competitive equilibrium (for pure private goods) and Foley's definition of the Lindahl equilibrium (for pure public goods) correspond to the special cases where the partition is P_1 or P_s. It is important to note that the Lindahl equilibirum is defined with respect to a given partition. In every case, Pareto optimality and inclusion in the core is proved only *relative to a partition*: there is no guarantee

[32] Modification of Foley's proofs, an elementary exercise, is left to the reader.

that the Lindahl equilibrium for some P_k will not be Pareto inferior or blocked by some allocation feasible under a different partition.

In the example used to establish Proposition 1, the Lindahl allocation corresponding to the partition $\{123\}$ was not in the core even though the only allocations in the core involve sharing of the public good by all three members of the economy.[33] It is natural to ask whether there is any other concept of equilibrium which is capable of sustaining allocations in the core. Fortunately, Foley has provided another concept of equilibrium which is much more flexible and appealing than Lindahl equilibrium, the public competitive equilibrium.[34] Translating his definition into our notation, we have for the pure public good case:

DEFINITION: *A pure public competitive equilibrium* is a feasible allocation $(g; x_1, \ldots, x_n)$, a price system $p=(p_g; p_x)$, and a vector of taxes $(t_1, \ldots, t_n)$ with $p_g g = \sum_{i=1}^{n} t_i$ such that:

(a)[35] $p\cdot(g; z) \geqq p\cdot(\bar{g}; \bar{z})$ for all $(\bar{g}; \bar{z}) \in Y(P_s)$;

(b) $p_x\cdot x_i = p_x\cdot w_i - t_i$ and if $(g; \bar{x}_i) \succ_i (g; x_i)$, then $p_x\cdot \bar{x}_i > p_x\cdot x_i$;

(c) there is no vector of public goods and taxes $(\bar{g}; \bar{t}_1, \ldots, \bar{t}_n)$

such that for every i there exists $\bar{x}_i$ with $(\bar{g}; \bar{x}_i) \succ_i (g; x_i)$ and $p_x\cdot\bar{x}_i \leqq p_x\cdot w_i - \bar{t}_i$.

In this definition, producers maximize profits, consumers maximize utility subject to their after-tax budget constraint, and there is no alternative level of public sector activity with taxes to pay for it that would make every consumer better off.

In extending this definition to an arbitrary partition P_k, we will also find it convenient to modify part (c) of Foley's version.[36]

DEFINITION: *A public competitive equilibrium under the partition P_k, $P_k=(J_1, \ldots, J_r)$*, is a feasible allocation $(g_1, \ldots, g_r; x_1, \ldots, x_n)$, a price system $p=(p_g^1, \ldots, p_g^r; p_x)$, and a vector of taxes $(t_1, \ldots, t_n)$ with $p_g^j g_j = \sum_{i\in J_j} t_i$ for all $j=1, \ldots, r$ such that:

(a) $\sum_{j=1}^{r} p_g^j g_j + p_x\cdot z \geqq \sum_{j=1}^{r} p_g^j \bar{g}_j + p_x\cdot\bar{z}$ for all $(\bar{g}_1, \ldots, \bar{g}_r; \bar{z}) \in Y(P_k)$;

(b) $p_x\cdot x_i = p_x\cdot w_i - t_i$ and if $(g_j; \bar{x}_i) \succ_i (g_j; x_i)$, then $p_x\cdot\bar{x}_i > p_x\cdot x_i$;

(c) for any $J_j, j=1, \ldots, r$, if $(\bar{g}_j; \bar{x}_i) \succ_i (g_j; x_i)$ for all $i \in J_j$,

then

$$p_g^j \bar{g}_j + \sum_{i\in J_j} p_x\cdot\bar{x}_i > p_g^j g_j + \sum_{i\in J_j} p_x\cdot x_i = \sum_{i\in J_j} p_x\cdot w_i$$

Conditions (a) and (b) have the same interpretation as the corresponding parts of Foley's definition; the budget of each jurisdiction is balanced; and if the members of a jurisdiction unanimously prefer some other allocation to the one they receive, then they cannot afford it at the given prices.[37] Foley's proofs are easily

[33] The Lindahl allocation is in the core only relative to the partition $\{123\}$: i.e., when blocking coalitions are unable to exclude nonmembers from consumption of the public good. It is worth emphasizing that the Lindahl equilibrium referred to in this example is precisely the Lindahl equilibrium as defined by Foley.

[34] Although mentioned in Foley (1970), a much more complete discussion of public competitive equilibria is contained in Foley (1967).

[35] Recall that we defined

$$z \equiv \sum_{i=1}^{n} (x_i - w_i)$$

[36] In the pure public goods case, the two definitions are equivalent.

[37] Do not confuse these prices (where there is one price for each jurisdiction) with the Lindahl prices (where there is one price for each individual). The Lindahl equilibrium is a special case of the public competitive equilibrium.

modified to demonstrate that the public competitive equilibrium for a partition P_k is Pareto optimal[38] and that for any Pareto optimum under the partition P_k there exists a supporting price system taking the form of a public competitive equilibrium.[39] It should be emphasized again that Pareto optimality is established only relative to a partition.

Since the Lindahl equilibrium is a public competitive equilibrium, we know that at least one public competitive equilibrium exists for any partition P_k. Proofs of existence for other types of public competitive equilibria could presumably be obtained for alternative theories of how the political decision-making process operates.[40]

Any imputation in the core can be sustained by some public competitive equilibrium. In the example used to establish Proposition 1, the core imputation $(u_1, u_2, u_3) = (2, 2, 11/16)$ can be achieved by a public competitive equilibrium with taxes $(t_1, t_2, t_3) = (14/15, 14/15, 19/30)$ and prices $p_x = 1$ and $p_g = 4/3$. The core imputation $(u_1, u_2, u_3) = (2, 39/16, 1/4)$ can be achieved by a public competitive equilibrium with taxes $(t_1, t_2, t_3) = (14/15, 21/30, 13/15)$ and prices $p_x = 1$ and $p_g = 4/3$.[41] Thus, the concept of a public competitive equilibrium offers much greater flexibility than the Lindahl equilibrium in adapting to the blocking power of coalitions.

The case of households treated as jurisdictions provides a useful illustration of the concept of a public competitive equilibrium. All that we have specified about the family decision-making process is that each family member maximizes his utility from goods consumed privately subject to the constraint of his "allowance" and that there is no combination of private and shared goods unanimously preferred to the bundle presently consumed by the family that it can afford. We have demonstrated that if the membership in households is considered exogenous to the model,[42] then public competitive equilibrium analysis can be applied. We have not reached a full reconciliation with standard competitive analysis, however. Consider the example of automobiles shared by members of a family. The definition of public competitive equilibrium permits a separate automobile price, p_g^i, for each household purchasing a car, but most economists would conclude that these prices will all be equal. It is reasonable to suppose, in this instance, that the resource cost of supplying a car to a family is independent of family size. In that case, condition (a) of the definition of a public competitive equilibrium implies that, for all families purchasing a car, the price must be equal; if prices were unequal, then selling all of the cars to the household having the highest p_g^i would be both feasible and more profitable. In this public competitive equilibrium, the marginal rates of substitution summed over the members of each family is equated to the marginal rate of transformation for the "public" good. Thus, the concept of a public competitive equilibrium provides a resolution

[38] See the proof in Foley (1967), pp. 60–61.

[39] See the proof in Foley (1970), pp. 68–69. As usual lump sum transfers may be required.

[40] Foley, for example, proves the existence of a public competitive equilibrium in the pure public goods case when taxes take the form of a proportional income tax (Foley (1967), pp. 71–72). However, the tax in the example used to establish Proposition 1 is a proportional income tax in the sense of Foley, so we also have a demonstration that proportional income taxes need not be in the core when public goods are crowded.

[41] The reader can verify that any imputation in the core for this example can be sustained by a public competitive equilibrium; in every case the price of the public good, p_g, equals the marginal cost of producing the public good.

[42] For example, we may assume that household membership is determined by social and cultural factors outside the scope of economic analysis.

to the problem raised by Samuelson in his paper on social indifference curves without resort to a family welfare function.

Samuelson has argued that a Lindahl equilibrium has "*no* relevance to motivated market behavior" (1969, p. 106). The fact that a Lindahl equilibrium may lie outside the core suggests that its political relevance is doubtful as well. The existence of a set of public competitive equilibria which support allocations in the core means that one does not have to rely on Lindahl equilibria to find a linkage between the allocation of public goods and a system of prices.

However, it is important to emphasize that a public competitive equilibrium has little value in itself as a solution concept.[43] In the case of a pure public good, for example, the set of public competitive equilibria coincides with the entire set of Pareto optima under that partition. To obtain a more determinate solution will, in general, require additional theory concerning the political process. There is little reason to believe that such processes bear any relation to Lindahl equilibrium.

VII. Global Lindahl Equilibrium

The two concepts of equilibrium discussed in this paper, the Lindahl equilibrium and the public competitive equilibrium, have been defined relative to the aggregate technology set, $Y(P_k)$, corresponding to a given partition P_k. As a consequence, Pareto optimality and inclusion in the core of the equilibrium allocations are proved only relative to the set of allocations achievable under P_k. There is no guarantee that such allocations will be Pareto optimal or in the core when alternative partitions are regarded as admissible.

However, if we were able to establish the existence of a *global* Lindahl equilibrium (i.e., a Lindahl equilibrium defined relative to the aggregate technology set

$$Y = \bigcup_{P_k \in \mathcal{P}} Y(P_k))$$

then stronger results would be available.

THEOREM 1: *If* $(g_1, \ldots, g_n; x_1, \ldots, x_n; p_g^1, \ldots, p_g^n; p_x)$ *is a global Lindahl equilibrium with respect to* w, *then it is in the core with respect to* w *and the aggregate technology set* Y.

PROOF:

Suppose that the coalition S could block $(g_1, \ldots, g_n; x_1, \ldots, x_n)$ by $(\bar{g}_1, \ldots, \bar{g}_n; \bar{x}_1, \ldots, \bar{x}_n)$. Since $(\bar{g}_i; \bar{x}_i) \succ_i (g_i; x_i)$ for all $i \in S$, the definition of a Lindahl equilibrium implies that

$$\sum_{i\in S} \overset{i}{p_g} \cdot \bar{g}_i + p_x \cdot \sum_{i \in S} \bar{x}_i > \sum_{i\in S} \overset{i}{p_g} \cdot g_i + p_x \cdot \sum_{i \in S} x_i = p_x \cdot \sum_{i\in S} w_i \tag{20}$$

or

$$\sum_{i\in S} \overset{i}{p_g} \cdot \bar{g}_i + p_x \cdot \sum_{i\in S} (\bar{x}_i - w_i) > 0 \tag{21}$$

But profit maximization, condition (a) in the definition of a Lindahl equilibrium, requires that

$$\sum_{i=1}^{n} \overset{i}{p_g} \cdot \bar{g}_i + p_x \cdot \bar{z} \leq 0 \quad \text{for all } (\bar{g}_1, \ldots, \bar{g}_n; \bar{z}) \in Y \tag{22}$$

This contradiction establishes the theorem. Letting $S = N$, it follows that the global Lindahl equilibrium is also globally Pareto optimal: i.e., Pareto optimal relative to the set of all allocations $(g_1, \ldots, g_n; z) \in Y$.

If a global Lindahl equilibrium exists, then much of our discussion in this paper would be superfluous; prices would guide the choice of partition as well as the

[43] I am grateful to a referee for stressing this point.

choice of an allocation under a given partition. Although nonconvexity of the aggregate technology set Y raises some doubts concerning existence of a global Lindahl equilibrium, convexity is not a necessary condition for existence. Is there something in the structure of our problem which will ensure existence of a global Lindahl equilibrium in the general case? Returning to our three-person economy, we can readily establish that this conjecture is false.

In the first place, if the core of the economy is empty, then no global Lindahl equilibrium can exist, and, in the course of demonstrating Proposition 2, we produced such a case. Furthermore, a global Lindahl equilibrium may fail to exist even when the core is not empty. Consider the example discussed in Section III where $w_1=w_2=2$, $w_3=1$, $a=b=1$, and $c=3/2$. The only allocation in the core is $(g_1, g_2, g_3; x_1, x_2, x_3)=(2, 2, 1/2; 1, 1, 1/2)$ corresponding to the partition $\{\{12\}, \{3\}\}$. This allocation is the Lindahl equilibrium relative to that partition with prices $p=(p_g^1, p_g^2, p_g^3; p_x)=(1/2, 1/2, 1; 1)$ where we arbitrarily set $p_x=1$. Note that

$$(23)\quad p\cdot(g_1, g_2, g_3; z)=p\cdot(2, 2, 1/2; -5/2)=0$$

For this equilibrium to be a *global* Lindahl equilibrium, we require

$$(24)\quad p\cdot(\bar{g}_1, \bar{g}_2, \bar{g}_3; \bar{z}) \leq 0 \quad \text{for all } (\bar{g}_1, \bar{g}_2, \bar{g}_3; \bar{z}) \in Y = \bigcup_{P_k\in\mathcal{P}} Y(P_k)$$

But $(\bar{g}_1, \bar{g}_2, \bar{g}_3; \bar{z})=(1/2, 2, 2; -5/2)\in Y$, where the allocation is achieved via the partition $\{\{1\}, \{23\}\}$, and

$$(25)\quad p\cdot(1/2, 2, 2; -5/2) = 3/4 > 0$$

Thus, no global Lindahl equilibrium exists which will sustain the only allocation in the core. We must conclude that, in general, no price system will exist to guide the choice of membership in jurisdictions, and, for that reason, we have defined our two concepts of equilibrium only relative to a given assignment of individuals into jurisdictions.

There is an interesting parallel between these results and the analysis of indivisibilities presented some time ago by Tjalling Koopmans and Martin Beckmann. They found that if the profitability of alternative locations for a given plant is independent of the location decisions of the other plants, then a system of location rents exists which supports a nonfractional assignment of plants to locations. But when profitability of alternative locations depends on the location decisions of the other plants—in their model, because of transportation costs—then no price system exists to guide the process of plant location. Prices have a limited role in explaining the organization of economic activity.

Koopmans and Beckmann stressed the importance of indivisibility to location theory in general:

> Finally, the theory of the location of economic activities has no chance of explaining such interesting realities as large and small cities without recognizing indivisibilities in the processes of production and human existence. [p. 53]

Neglect of indivisibilities, or nonconvexities, explains why the application of general equilibrium analysis to location theory has not been very fruitful. By presupposing the existence of a price system and well-defined demand or supply functions at each location, the location problem is essentially assumed away. Locations are implicitly fixed. It is for this reason that location theorists find it necessary to turn to vague notions of agglomeration or urbanization economies when they try to explain the phenomena they observe. Location theory cannot be brought within the province of general equilibrium analysis solely by adding a subscript to the conventional competitive model.

VIII. Buchanan's Theory of Clubs

A reader familiar with the work of Buchanan will by now recognize that the treatment of public goods in this paper is closely related to his theory of clubs. What I have defined as a jurisdiction, Buchanan calls a club. It is appropriate, at this point, to indicate the relationship between our respective approaches.

In the discussion so far, I have permitted crowding in the *production* of public goods but excluded the effects of crowding from individual utility functions. Specifically, I have assumed that individuals are indifferent concerning the number of other consumers sharing consumption of the public good. Buchanan, on the other hand, allows crowding to affect utility functions as well as production functions. My reason for avoiding this complication has been solely for purposes of simplifying the exposition. The model is easily extended to incorporate this additional element of crowding.

Introducing a crowding parameter, the number of individuals in a jurisdiction, into utility functions requires no change in the definition of a Lindahl or a public competitive equilibrium for a given partition P_k. Since jurisdictional size is by definition fixed, the effect of this parameter is incorporated into the preference orderings. In analyzing choice among partitions, the presence of crowding in utility functions means that the appropriate preference orderings to consider depend on the partition. Our conclusion that prices have little relevance to the selection of a partition is, if anything, reinforced by the dependence of individual preference orderings on the partition chosen.

Permitting crowding to affect preference orderings does enhance the realism of the model. Turning to an example used before, it is reasonable to expect that, holding wealth constant, larger households will purchase more cars. If a household is wealthy enough and sensitive enough to crowding, it may no longer be the preferred jurisdiction for automobile consumption: husband and wife will have their "own" car and the teenage son will use summer earnings to buy a hot rod.

From our perspective, the theory of clubs emerges as even more general than Buchanan is willing to claim. He asserts that:

> The procedure implies that the individual remains indifferent as to which of his neighbors or fellow citizens join him in such arrangements. In other words, no attempt has been made to allow for personal selectivity or discrimination in the models. To incorporate this element, which is no doubt important in many instances, would introduce a wholly new dimension into the analysis, and additional tools to those employed here would be required. [p. 13, fn. 1]

Our analysis demonstrates that introducing preference for particular individuals as members of one's jurisdiction—on the basis of race, religion or sex—is not essentially different from the introduction of crowding into the analysis.[44]

There is one area of substantial disagreement between the approaches of Buchanan and myself. He states as a necessary condition for Pareto optimality ". . . that the marginal rate of substitution 'in consumption' between the size of the group sharing in the use of X_j and the numeraire good, X_r, must be equal to the marginal rate of substitution 'in production' " (p. 5). Our analysis indicates, however, that determining the "optimal" partition—whether defined as Pareto optimal or in the core—requires *global* rather than marginal comparison of alternative sharing patterns. To any arbitrarily chosen partition there corresponds a price system which supports a public competitive equilibrium. The equi-

[44] Of course, in particular extensions of this analysis the assumption that preferences depend only upon crowding and the wealth and tastes of the other members may be a useful simplification.

librium allocation is Pareto optimal with respect to the set of allocations feasible under the given partition. However, under some other partition allocations may exist which are Pareto superior to the public competitive allocation or which permit some coalition to block. The presence of nonconvexity means that the price system is no longer a reliable guide to the attainment of allocations that are Pareto optimal and in the core. Decision making cannot be completely decentralized to the level of individual agents responding marginally to market prices. The search for the optimal pattern of sharing of public goods requires the global comparison of the allocations achievable under each alternative partition.

The Supply of Rental Housing: Comment

By RONALD E. GRIESON*

In a recent issue of this *Review*, Frank de Leeuw and Nkanta Ekanem (L-E) proposed to determine whether the marginal cost of housing is constant or rising as a function "of the amount of housing services provided in an area."

I propose to show that a nonrising supply curve is inconsistent with positive long-run land prices and to show that the L-E housing supply elasticities, calculated from reduced form equations, are very sensitive to the specification of the true supply and demand functions. An alternative and perhaps more reasonable a priori specification is herein set out which is then used to calculate much different elasticities of supply.

These alternatively calculated coefficients are elastic, rather than inelastic as deduced by L-E, and consistent with estimates which I have made in another paper, and with the reduced form estimated by the authors. The L-E model and estimates are shown to suffer from misspecification, statistical inconsistency, and multicollinearity.

I. Consistency of the Hypothesis

If more housing could be produced in a given land area at constant cost, then the existing housing stock could be constructed at equal cost on a smaller area of land. Hence land having no marginal product would earn no rent.[1] Of course the authors may not have been precise in their use of the word "area."

II. The Econometric Model

L-E postulate the following demand and supply equations for housing, (12) and (13),[2] respectively:

$$(S - H) = \alpha_1 + \beta_1 Y - \beta_2(R - P) \tag{12}$$

$$R = \alpha_2 + \beta_3 C + \beta_4 O + \beta_5(S - H) + \beta_6 H \tag{13}$$

All variables measured in logarithmic form:

S = the quantity of housing services
H = the number of households
Y = real income
R = rents per unit of housing services
P = the price level of nonhousing goods and services
C = the price of capital inputs
O = the price of operating inputs

The authors cite a study by de Leeuw in which the income and price elasticities of rental housing are calculated as $+1.0$ and -1.0, respectively. They argue that with minor qualification this permits β_1 and β_2 to be set (approximately) equal to 1.0. Setting β_1 and β_2 equal to 1.0 and solving (12) and (13) for R leads to the reduced form:

$$R = \left(\frac{\alpha_2 + \alpha_1\beta_5}{1+\beta_5}\right) + \left(\frac{\beta_3}{1+\beta_5}\right)C + \left(\frac{\beta_4}{1+\beta_5}\right)O + \left(\frac{\beta_5}{1+\beta_5}\right)(Y+P) + \left(\frac{\beta_6}{1+\beta_5}\right)H \tag{14}$$

They then proceed to estimate (14) for low income housing, R_1, moderate income housing, R_2, and high income housing, R_3. For example,

$$\underset{}{R_1} = \underset{(2.0)}{2.33} + \underset{(3.9)}{.321C} + \underset{(2.1)}{.183\,O} + \underset{(4.0)}{.593(Y+P)} - \underset{(-2.6)}{.036H} \qquad (R^2 = .70) \tag{15}$$

They calculate $\beta_5 = 1.46$ and the elasticity of supply of housing equal to $(1/\beta_5) = 0.7$

* Assistant professor of economics, Queens College, City University of New York.

[1] For a fuller explanation of this point, see Grieson.

[2] Equation numbers are those used by de Leeuw and Ekanem except for primed numbers which are mine.

TABLE 1—ALTERNATIVELY CALCULATED PARAMETERS

Equation	β_3	β_4	β_5	Elasticity of supply $=1/\beta_5$	A priori coefficient of $P=(1-\beta_3-\beta_4+\beta_5)/(1+\beta_5)$	Actual coefficient of P, t-ratio below
(9) low income housing, R_1	.21	.14	.45	2.2	.76	.89 (2.1)
(10) moderate income, R_2	.19	.08	.54	1.8	.83	1.00 (2.0)
(11) high income, R_3	.53	−.37	2.7	.37	.96	1.26 (1.7)

(0.5 and 0.3 for R_2 and R_3, respectively). These values are very low and much below those Muth and I have reported.

Using the same notation, let us now postulate the following alternate set of demand and supply equations, which can be estimated from reduced forms calculated by L-E and which demonstrates the sensitivity of their results to changes in a priori specification.

$$(1') \quad (S - H) = \alpha_1 + \beta_1 Y - \beta_2(R - P)$$

$$(2') \quad R - P = \alpha_2 + \beta_3(C - P) + \beta_4(O - P) + \beta_5(S - H)$$

These equations seem more reasonable since there is no reason to include H in the supply equation as L-E did, obtaining difficult to explain negative coefficients. Furthermore R and perhaps C, and O ought to be deflated by P à la the authors' deflation of R by P in the demand equation (1). Setting $\beta_1=\beta_2=1$ again and solving (1′) and (2′) for R we obtain:

$$(3') \quad R=\frac{\alpha_2+\alpha_1\beta_5}{1+\beta_5}+\frac{\beta_3 C}{1+\beta_5}+\frac{\beta_4 O}{1+\beta_5}+\frac{\beta_5 Y}{1+\beta_5} + \frac{(1-\beta_3-\beta_4+\beta_5)}{(1+\beta_5)}P$$

which would be estimated as:

$$(4') \quad R = d_i + d_{i1}P + d_{i2}Y + d_{i3}C + d_{i4}O$$

L-E have estimated this reduced form obtaining the following three equations with the t-ratio shown in parentheses below coefficients:

$$(9) \quad \underset{(4.1)}{R_1 = 4.39} + \underset{(2.1)}{.89P} + \underset{(2.4)}{.31Y} + \underset{(3.3)}{.31C} + \underset{(2.2)}{.20O}, \qquad R^2 = .66$$

$$(10) \quad \underset{(3.3)}{R_2 = 4.32} + \underset{(2.0)}{1.00P} + \underset{(2.2)}{.35Y} + \underset{(2.4)}{.27C} + \underset{(1.1)}{.12O}, \qquad R^2 = .54$$

$$(11) \quad \underset{(1.8)}{R_3 = 1.59} + \underset{(1.7)}{1.26P} + \underset{(3.1)}{.73Y} + \underset{(.8)}{.14C} - \underset{(-.6)}{.10O}, \qquad R^2 = .36$$

We can now set $d_{i2}=(\beta_5/1+\beta_5)$ finding β_5 and the elasticity of supply of housing equal to $(1/\beta_5)$. We can also solve for $\beta_3=(1+\beta_5)d_{i3}$ and $\beta_4=(1+\beta_5)d_{i4}$, from which we can obtain a priori estimates of d_{i1}, the coefficients of P, equal to $(1-\beta_3-\beta_4+\beta_5)/(1+\beta_5)$, providing an econometric test for our a priori model. Using this a priori specification and equations (9)–(11), we calculate the following alternate parameters (shown in Table 1).

A simpler alternative specification of the supply function is:

$$(5') \quad (R - P) = \alpha_2 + \beta_3 C + \beta_4 O + \beta_5(S - H)$$

Again, assuming $\beta_1=\beta_2=1$ and substituting from the demand equation (1′) yields:

$$(6') \quad R = \frac{\alpha_2 + \alpha_1\beta_5}{1+\beta_5} + \frac{\beta_3 C}{1+\beta_5} + \frac{\beta_4 O}{1+\beta_5} + \frac{\beta_5 Y}{1+\beta_5} + P$$

All coefficients except that of P stay the same while our a priori prediction of the coefficient of P becomes one. The calculated coefficients of P and the t-ratios in L-E's equations (9), (10), and (11) are, respectively, .89 ($t=2.1$), 1.00 ($t=2.0$) and 1.25 ($t=1.7$). Hence, our second alternative model also fits L-E's estimates extremely well.

The a priori assertion that the coefficient of P is equal to $(1-\beta_3-\beta_4+\beta_5)/(1+\beta_5)$ or one is held up by equations (9)–(11), but the L-E assertion that the coefficients of Y and P are the same does not seem to be. They have put H into equations (15)–(16) and defined a new variable $Y+P$, but the absence of H should not really be of great importance in determining the coefficients[3] of (9)–(11) where we can examine the hypothesis that the coefficients of P and Y are the same. L-E have not made such examination.

TABLE 2—COMPARISONS OF Y AND P COEFFICIENTS

Equation	Coefficient Y	Coefficient P
(9)	0.31 (2.4)	0.89 (2.1)
(10)	0.35 (2.2)	1.00 (2.0)
(11)	0.73 (3.1)	1.26 (1.7)

Though we cannot test whether the coefficients of P and Y are significantly different without knowing their covariance, we can say that they appear so at the 10 percent level assuming no covariance. Positive covariance as is likely would probably show them significantly different at the 5 percent level or higher.

[3] The assumption is supported by the observation that the coefficients of O and C are not significantly affected by the inclusion or exclusion of H. For example, compare (9)–(11) and (15)–(17).

The a priori model of supply which would best fit land value theory would divide the supply of housing services variable, S, by the quantity of land upon which S is located, T_s, as follows.

$$(7') \quad R - P = \alpha_1 + \beta_3 C + \beta_4 O + \beta_5 (S - T_s)$$

III. Conclusions

First we have briefly explained why recent theoretical findings show the L-E hypothesis of constant cost of increasing the amount of housing services on a given land area is inconsistent with the existence of positive land values. We have gone on to suggest the use of housing structures per unit land as a variable which should have been used to reflect the above fact.

Secondly, we pose two reasonable alternative specifications of the supply function which would yield reduced form equations of a type estimated by L-E. Using these alternative specifications we obtain estimates of the elasticities of supply of housing and a priori predict the coefficients of P found in the actual reduced form. The ability to predict the coefficients of P indicates that our alternative specification is likely to be superior to those postulated by L-E which predict the coefficients of P and Y equal in apparent contradiction of the estimated parameters.

The second alternative specification advanced in this paper predicts the coefficient of P as always being one while the first alternative specification predicts P coefficients of .76 to .96. The coefficients calculated by L-E are .89, 1.00, and 1.26; none of which is significantly different from either alternative specification and all of which are significantly different from the P coefficient calculated by L-E when they force the coefficient of P and Y to be equal.

The elasticities of supply calculated using our alternative specification and the reduced form estimators for low and moderate rental housing are 2.2 and 1.8 compared to .7 and .5, respectively, calculated by L-E. Supply elasticities of 2.36 to 5.00 are predicted in my earlier work when land is about one-fifth to one-tenth of the value of structure plus

land[4] where the elasticity of supply of structures is one-half of the ratio of total cost to land cost;

$$E_s = \frac{1}{2}\,\frac{\text{Total Value}}{\text{Land Value}}$$

The estimated equations for high income housing, (11) and (17), yield supply elasticities of .3 for L-E and .37 for the alternative specification. These estimators are the most econometrically suspect, since the coefficient of O, the *log* of the price of operating inputs, turns "negative". The t-ratios for O, C, and P drop to $-.6$, .8 and 1.7, respectively, in equation (11) from 2.2, 3.3, and 2.1 in equation (9), while the R^2 drops to .36 from .54 and .66 in equations (9), (10), and (11), respectively.

Examining the authors' specifications of the reduced form,

$$\text{(15)}\quad \underset{(2.0)}{R_1 = 2.33} + \underset{(3.9)}{.321C} + \underset{(2.1)}{.183O} + \underset{(4.0)}{.593(Y+P)} - \underset{(-2.6)}{.036H} \qquad (R^2 = .70)$$

$$\text{(17)}\quad \underset{(.6)}{R_3 = 1.43} + \underset{(1.1)}{.178C} - \underset{(-.4)}{.066O} + \underset{(2.6)}{.745(Y+P)} + \underset{(.2)}{.004H} \qquad (R^2 = .35)$$

[4] The one-fifth figure is based upon HUD data for new homes built in the United States in 1970. The one-tenth figure is based on the land content of high-rise apartment buildings.

we see the same dramatic drop in: the t-ratios of all variables; the coefficient of O to negative; and the R^2.

The explanation of this difficulty would seem to be that variables O, C, P, and perhaps Y suffer from multicollinearity in equation (11) and (17). The coefficients of C and O are dropping to below their true value as the coefficients of Y and P are rising above their true values. Thus the coefficients of P and Y are too high and the elasticity estimates, $1/\beta_5$, too low in these equations, though it would not be surprising to find the elasticity of supply of high rent housing somewhat more inelastic than that for low rent housing, since it is easier to depreciate existing housing downward than it is to upgrade low quality housing. High income housing may also have a higher component of historic, artistic, and cultural resources which are difficult to duplicate, thereby reducing supply elasticity.

This multicollinearity may have also lowered the estimates of supply elasticity for moderate and to a lesser extent low income housing. Hence, the supply elasticity of 2.2 estimated for low income housing is the most significant by all criteria and the closest to those which I estimated.

The Supply of Rental Housing: Reply

By Frank de Leeuw and Nkanta F. Ekanem*

Ronald Grieson comments on two aspects of our paper: the plausibility of its results, and the interpretation of its empirical findings.

On empirical findings, we have no strong preference for our interpretation over Grieson's. He shows, in essence, that if the general price level enters the supply function as well as the demand function, then our regression coefficients may imply elasticities of supply somewhat higher than the ones we presented. The elasticities we presented ranged from .3 to .7; the ones he presents range from .4 to 2.2. Both Grieson's interpretation and ours lead to the same principal conclusion; namely, that " . . . the long-run supply of housing services is less than perfectly elastic" (see de Leeuw and Ekanem, p. 812). Both sets of elasticity estimates suffer from the problems of measurement error which our article discussed.

An advantage of Grieson's interpretation is that it implies higher reduced-form coefficients for the price level than for income per household, which fits the data better than our specification. One disadvantage of his interpretation is that there is no clear theoretical basis for including the general price level in the supply function; if the supply function is the result of profit maximization subject to a production function for converting capital and operating inputs into housing services, then the only relevant prices would seem to be those of housing services, capital inputs, and operating inputs (all of which were already included in our specification). Possibly the general price level serves as a proxy for prices of inputs not covered by our measures. But surely the general price level does not belong in the supply function simply because it appears in the demand function, as Grieson seems to argue.

On the plausibility of results, we have reservations about Grieson's position. He finds a long-run rising supply price for housing services plausible because of the inelastic supply of land. Both our elasticity estimates and his, however, refer to the elasticity of supply *holding constant* the price of land as well as prices of other inputs. (See de Leeuw and Ekanem, pp. 808, 810.) Hence, the explanation of our findings cannot be the tendency for the price of land to rise as housing demand shifts upward.

We suspect that the explanation of our findings lies in diseconomies of scale in the maintenance, improvement, and conversion of existing housing capital. To understand the connection between these activities and our study it is useful to distinguish between two meanings of "long run" in the housing market. The first is a time period long enough for the total *quantity* of housing capital in a housing market to respond fully to changes in underlying conditions—a period whose length has been estimated to be of the order of magnitude of six years. (See Richard Muth, p. 76.) The second is a time period long enough for not just the quantity, but the *form* of existing housing capital—number of units per building, architectural style, location pattern within a housing market area, and so forth—to respond fully to changes in underlying conditions. The second long run is surely a great deal longer than six years.

We believe that the results of our study apply to the first rather than the second of these long runs. In the second long run, at least under competitive conditions, prices per unit of housing service presumably approach new construction prices (plus local land rents) for all types of housing. Since the construction of new housing is a replicable process, we might expect (input prices aside) constant returns to scale to characterize, at least approximately, this long run.

In the first long run, however, there could be important quasi rents—positive or nega-

* The Urban Institute.

tive—for particular types or quality levels of existing housing, arising from diseconomies of scale in altering capital which has already been embodied in a specific form and location. Since we believe that this process of altering existing capital constitutes a significant part of what we observe in our cross-section study, we feel that it may well be the source of the rising supply price we observe across metropolitan housing markets.

Property Crime and Economic Behavior: Some Empirical Results

By DAVID LAWRENCE SJOQUIST*

Belton Fleisher and Gary Becker have previously suggested that crime may be explainable, at least in part, by economic theory. This paper will consider this possibility for the crimes of robbery, burglary, and larceny over $50.[1] The hypothesis to be tested is that under some conditions, criminals can be treated as rational economic beings, assumed to behave in the same economic manner as any other individual making an economic decision under risk.

In Section I we develop an economic model of criminal behavior; Section II is devoted to a discussion of the problems involved in testing the model; and Section III is concerned with the results of the empirical analysis.

I. An Economic Model of Criminal Behavior

Given a fixed amount of time, t, an individual must choose between those various activities which consume time. For our purposes, let us assume there are two time-consuming activities or forms of behavior, one of which is legal,[2] i.e., work, and the other illegal, i.e., crimes against property. Our task is to explain how the individual allocates his time between the two activities. It is expected that this depends on the gains and costs involved in the two activities.

Participation in the two activities is expected to result in psychic and financial gains and costs. The gain per unit of time from legal activity is measured by the individual's wage rate, g_w, which is assumed to be constant and to include any psychic gain. The individual's total gain from legal activity, $\bar{g}_w$, therefore equals the time allocated to that activity, t_w, times the wage rate. We assume that g_w is generated with certainty with all associated costs both financial and psychic included.

Participation in illegal activities results in a psychic and/or financial gain. The psychic gain is measured by that quantity of money which the individual is willing to pay to obtain the psychic gain. The financial gain is measured directly by the dollar value to the criminal of the assets stolen.[3]

Since a crime could be unsuccessful, the gain from illegal activity, particularly the financial gain, is random with the individual normally possessing a subjective probability distribution of the possible gains. We will simplify however, by assuming that the gain is generated with certainty. We will also assume that the wage rate from crime, g_c, is constant and includes any psychic gain so that the total gain from illegal activity, $\bar{g}_c$, is equal to the time spent in illegal activity, t_c, times the wage rate from crime.[4] All costs of illegal activity, both financial and psychic, other than those associated with arrest, conviction, and punishment, are included in g_c.

Besides any expenditures for tools, etc., illegal activity involves the possibility of costs resulting from arrest, conviction, and punishment. These include public scandal, loss of freedom, the distaste of prison life, lawyer fees, possible reduction in potential income, since individuals possessing crim-

* Assistant professor of economics, Georgia State University. James Simler, Raymond Galvin, James Weatherby, Barbara Zoloth, and Larry Schroeder for many helpful comments.

[1] For a definition of these crimes, see Federal Bureau of Investigation (FBI), *Reports*, pp. 13–26.

[2] If leisure and work are equally valued at the margin then we need only consider one of them as the legal activity.

[3] Since nonfinancial assets are normally distributed through a black market, the value to the criminal will not necessarily be the same as the loss of the victim.

[4] Assume $t_w, t_c \geq 0$, $t > 0$ and $t_w + t_c = t$.

inal records find it more difficult to obtain employment, and loss of earnings while imprisoned, measured by the discounted value of income foregone while in prison less any benefits received, such as room and board and vocational training.

The psychic and financial costs associated with arrest and conviction are assumed to be quasi-fixed costs, that is, if arrested and convicted, the cost is the same regardless of the time the individual spent in illegal activity.[5]

The costs associated with imprisonment are variable and depend upon the length of the sentence served and the individual's legal wage rate. Assuming that the expected length of the sentence received is positively related to the time spent in illegal activity,[6] and that the length of the sentence received is positively related to the length of the sentence actually served, we can conclude that the expected cost of imprisonment depends upon the legal wage rate and the time spent in illegal activity. (There is a substantial amount of evidence indicating that variance in sentencing is large,[7] implying the existence of a probability distribution of possible costs from imprisonment, given that arrest and conviction have taken place. We will, however, disregard this and assume that there is no uncertainty as to the sentence received.)

We then have the total cost of illegal activity, $\bar{p}$, composed of a quasi-fixed cost component, p^*, and a variable cost component, $\hat{p}=\hat{p}\,(g_w, t_c)$. Thus, $\bar{p}=p^*+\hat{p}\,(g_w, t_c)$. Assume for simplicity that $\partial\hat{p}(g_w, t_c)/\partial t_c=p$ and is constant.

All crimes do not result in arrest and conviction, meaning that the cost of illegal activity occurs according to some probability distribution. Individuals are assumed to possess a subjective evaluation of the probabilities of arrest, of conviction, and of imprisonment. Although these probabilities no doubt depend upon the time spent in illegal activity, we will assume they are constant. Since nothing is lost in the analysis by doing so, we will also assume temporarily that the probability of conviction and punishment, conditioned on arrest, is one. Thus the joint probability of arrest, conviction, and punishment equals the probability of arrest.

The gains and costs from legal and illegal activities are evaluated by the individual according to his preference ordering, taking into account the various probabilities. We assume that this preference ordering is a Von Neumann-Morgenstern measurable utility function, that is, under conditions involving risk, individuals will choose between alternatives so as to maximize the expected value of utility.

There exist two possible states of nature, the individual will either be arrested and therefore convicted and punished, or not arrested. Let $U(\bar{g}_w+\bar{g}_c)$ represent the ordinal utility if not arrested, and $U(\bar{g}_w+\bar{g}_c-\bar{p})$ represent the ordinal utility if arrested, where the utility index is appropriately chosen in accordance with the Von Neumann-Morgenstern axioms. Let r represent the probability of arrest, conviction, and punishment; that is, the probability of incurring those financial and psychic costs associated with arrest, conviction, and punishment. The expected total utility is thus:

$$E(U) = (1-r)U(\bar{g}_w+\bar{g}_c) + rU(\bar{g}_w+\bar{g}_c-\bar{p}) \tag{1}$$

which is to be maximized subject to the constraint $t=t_w+t_c$.

The first-order conditions for maximization require that

$$\frac{g_w-g_c}{g_c-g_w-p} = \frac{(1-r)U_1'}{rU_2'} \tag{2}$$

where

$$U_1' = \frac{dU(\bar{g}_w+\bar{g}_c)}{d(\bar{g}_w+\bar{g}_c)}$$

[5] If the quasi-fixed costs are large, then an increase in the length of the sentence increases total cost by a small percent. The effect then would be for variations in the length of the sentence to have little influence on the amount of time spent in illegal activity.

[6] For a study of sentencing which yields this result, see Edward Green.

[7] See Glendon Schubert.

and

$$U_2' = \frac{dU(\bar{g}_w + \bar{g}_c - \bar{p})}{d(\bar{g}_w + \bar{g}_c - \bar{p})}$$

Assuming U_1', $U_2'>0$, then condition (2) holds if

$$g_c - g_w < p \tag{3}$$

It should be pointed out that a corner solution at $t_w = t$ is quite possible because of the quasi-fixed cost of illegal activity.

The second-order condition requires that

$$(1 - r)U_1''[g_c - g_w]^2 + rU_2''[g_c - g_w - p]^2 < 0, \tag{4}$$

where U_1'', U_2'' refer to the second derivatives. A sufficient condition for (4) to hold is that the individual is risk averse, i.e., U_1'', $U_2''<0$. If an individual has a strong enough preference for risk the indifference curves will be concave, in which case the individual will either specialize in work or crime.

The question we wish to ask is: How do people respond to changes in risk, wages, and punishment? If the individual is risk averse, then given our previous assumptions, it can be shown that $dt_w/dr>0$, i.e., an increase in r reduces the time spent in illegal activity. However if the indifference curves are concave then a person who was specializing in work will now specialize in crime, if the change in r is large enough. Likewise it can be shown that for an individual who is risk averse we would have $dt_w/dg_c<0$, $dt_w/dg_w>0$, and $dt_w/dp>0$.

II. Testing the Model

The time spent in criminal activity by the ith individual, t_c^i, can be expressed as a function of the variables specified in the previous section, namely,

$$t_c^i = f^i(r^i, p^i, g_w^i, g_c^i; x^i) \tag{5}$$

where x^i is an index of variables which "measures" tastes, and the other variables are as previously defined.

Assume that this function has the following explicit form:

$$t^i = \alpha_0 r^{i\alpha_1^i} g_w^{i\alpha_2^i} g_c^{i\alpha_3^i} p^{i\alpha_4^i} x^{i\alpha_5^i} \tag{6}$$

The model is specified in terms of individual behavior, while the available data are community aggregates. Taking the natural *logs* of (6) and replacing individual values by community means we have

$$ln\,(TC/I) = ln\,\alpha_0 + \alpha_1\,ln\,r + \alpha_2\,ln\,GW + \alpha_3\,ln\,GC + \alpha_4\,ln\,P + \alpha_5\,ln\,X \tag{7}$$

where (TC/I), GW, GC, P, and X represent population means of t_c, g_w, g_c, p, and x, respectively, TC is the total time spent in illegal activity and I is the community population. The values of the parameters of (7) will be the same as the parameters of (6) if we assume that the values of the parameters of (6) are the same for all individuals in a given community[8] and that the density function between individual values and the community mean of the variable are homogeneous of degree one with respect to changes in the individual values and community means.[9]

A cross-sectional sample of 53 municipalities with 1960 populations of 25,000 to 200,000 was selected on the basis of the following criteria:

1. We eliminated communities with 1960 populations of less than 25,000 because of a lack of data, and of more than 200,000 in order to use communities which were internally homogeneous.
2. To minimize spillover effects, any community with neighboring communities of 25,000 or more was eliminated, as well as any community with less than 50 percent of the population of its Standard Metropolitan Statistical Area (*SMSA*).

Of the 75 communities which fulfilled these criteria, 22 had to be dropped for lack of information on arrests.

Since it is not possible to directly measure the time spent in illegal activity, we measured the amount of illegal activity by the

[8] For a proof see Henri Theil, p. 142.
[9] See James Tobin, p. 126.

total number of property crimes committed, N. This in turn was measured by the total number of the three types of property crimes recorded by the local police department as reported in the 1968 FBI *Reports*.

The data on reported crimes is subject to strong criticism[10] and hence one must be very cautious in drawing implications using this data.

The FBI supplied unpublished information, collected yearly from local police departments, which we used to measure arrests and convictions at the local level for the year 1968. The number of convictions was similarly estimated[11] for 1968 from this information.[12]

We employed three separate measures of r: the ratio of arrests to the number of crimes; the ratio of convictions to the number of crimes; and the ratio of convictions to arrests. These measure, respectively, the probability of arrest, $r(A)$, the probability of conviction, $r(AC)$, and the probability of conviction given arrest, $r(C|A)$.

When the ratio of arrests or convictions to reported crimes is used to measure r, reported crimes appear in both the dependent and the independent variable. Thus to the extent that there are errors in the measure of reported crimes, we expect a bias in the coefficients of that equation.

The net gain from legal activity, GW, was measured by the annual labor income to manufacturing workers in 1968. These are county-wide data and were obtained from the 1968 *County Business Patterns*.[13]

It is not possible to differentiate the incomes of criminals from the incomes of victims, which poses a problem in measuring the gain from legal activity. To the extent that crimes against high income individuals yield greater returns to the criminal, we would expect a positive correlation to exist between income and the number of crimes. If this is true then use of mean community income is not a good measure of the opportunity cost of committing crime. In addition to mean income therefore, we also employed substitute variables: the 1968 labor force unemployment rate, derived from information published by the Bureau of Labor Statistics, and the percent of families with income below \$3,000, taken from the 1960 *Census of Population*. An unemployed person has more time to allocate to illegal activity and since his current income is low, he would have a greater incentive to commit crimes. The same reasoning can be applied to a family with a low income.

We have been unable to find any information on the financial loss of the public from criminal activity, other than a national average for each classification of crime. As a substitute variable we used retail sales per establishment reasoning that the size of the expected gain depends upon the size of the establishment a criminal chooses to rob or burglarize.

We assumed that the only variable cost of illegal activity is the cost of punishment, which depends upon the income foregone while in prison less benefits, and any psychic costs. The discounted value of the foregone earnings is highly correlated with current earnings thus we cannot use both in our regression equation. Given the mean income for the community, the foregone earnings will be proportional to the length of the sentence served. Thus the length of the sentence served can be used to reflect the cost of illegal activity. (Since we had no measure of the psychic costs, we had to ignore them.)

[10] For a discussion of the problems with crime data see Thorsten Sellin and Marvin E. Wolfgang, pp. 71–86, and The National Opinion Research Center *Report*.

[11] Convictions were determined in the following manner: A conviction rate was found using the ratio of persons guilty to the sum of persons guilty and acquitted. This ratio was then applied to those cases not yet brought to court. The number of convictions was then the sum of this product, the number guilty and the number sent to juvenile court.

[12] Using the number of arrests and convictions and the number of crimes for the same period does not take into account time lag between the criminal act and the arrest and the resulting conviction. This may result in erroneous measures of r.

[13] The size of the city and the method of selection of the sample resulted in a sample for which differences between the city and the rest of the county was minimized, so that the problem of using county-wide data is minimal.

To measure the average sentence served, we used the reported state-wide average time served by inmates released from state and federal prisons in 1960, for the crimes we are considering, as published by the Federal Bureau of Prisons. Figures other than state-wide averages or beyond 1960 were not available.[14]

A number of variables was employed to reflect economic and demographic differences between communities as well as to reflect possible differences in the evaluation of the psychic gains and costs. The percent of the population which is nonwhite reflects the income distribution and regional differences, since in our sample the percent nonwhite decreases as one moves from the South to the Northeast, to the West, to the Midwest. The mean number of school years completed reflects both cultural differences and differences in expectations of future incomes. We employed population density to reflect the fact that the closer the opportunities are, the greater the likelihood the individual can acquire the information necessary to perform a crime. Finally, we included population as a factor because of possible differences in the social make-up of residents of different sized cities.

Thus we arrive at the equation we estimated:

$$(8)\quad (N/I) = \beta_0 r^{\beta_1} S^{\beta_2} GW^{\beta_3} E^{\beta_4} NW^{\beta_5} SY^{\beta_6} D^{\beta_7} I^{\beta_8} \phi$$

where N, r, GW, and I are as previously defined, S is the average prison sentence served, E is retail sales per establishment, NW is the percent nonwhite, SY is the mean school years completed, D is population density, and ϕ is a random error term assumed to have a lognormal distribution.

[14] We feel the assumption that the same sentence is served by all criminals for a particular crime in a given state regardless of the community is not unreasonable. We know that the variance in the sentence served across states is substantially less than the variance in the sentence imposed. In addition, since paroles are normally granted by one agency for all state prisons in a particular state, we expect even more uniformity in the sentence served than in the sentence imposed.

III. Results of the Statistical Analysis

Using multiple regression analysis, we estimated the parameters of equation (8) using the total of the reported property crimes in the three categories, robbery, burglary, and larceny over \$50 to measure N and employing three different measures of risk: $r(A)$, $r(AC)$, and $r(C|A)$. (We are assuming that if convicted the individual is punished.) The results of the regressions are presented in Table 1.

It was implied from our model that the coefficients of the measure of risk should be negative and as seen in Table 1 the coefficients are of that sign. However, when r is measured by $r(A)$ and $r(AC)$ the coefficients are biased, as indicated above. Note though, that the coefficient for convictions per arrest, which is not biased, is also negative.

According to the theory, an increase in r reduces the amount of crime because it increases the expected cost and therefore lowers expected utility from crime. Separate increases in the three measures of risk result in increases in different costs. We thus expect the elasticity of N with respect to risk to be higher for $r(AC)$ than for $r(A)$ given $r(C|A)$, and for $r(C|A)$ given $r(A)$. It is also expected that the elasticity for $r(C|A)$ would be less than the elasticity for $r(A)$, given our discussion of cost in Section I.

Equation 4) of Table 1 presents the results of a regression in which both $r(C|A)$ and $r(A)$ were used. Comparing equation 4) with equation 2), we see that the elasticity for $r(C|A)$ is smaller than the elasticity for $r(AC)$ as expected, though not significantly. The elasticity for $r(A)$, however, is slightly larger than the elasticity for $r(AC)$. We note also from equation 4) that elasticity for $r(C|A)$ is less than the elasticity for $r(A)$, but again not significantly.

The coefficient for average sentence served, S, is negative for all equations in Table 1, a result our theory leads us to expect.

In equation 4), we note that the elasticity of N/I is greater with respect to $r(A)$ than with respect to S, but not significantly. If we assume risk aversion, i.e., that the ex-

* Significant at the 10 percent level with a one-tailed test.

N = Total number of robberies, burglaries and larcenies over \$50 in 1968 reported to the FBI by local police.

A = Number of arrests in 1968 for the crimes of robbery, burglary and larceny over \$50 as reported to the FBI by local police departments.

C = Number of convictions in 1968 for the crimes of robbery, burglary, larceny over \$50 as reported by the local police to the FBI.

$r(A) = A/N$

$r(AC) = C/N$

$r(C|A) = C/A$

GW = Yearly income in thousands of dollars from the 1968 *County Business Patterns;* county wide.

E = Yearly sales per retail establishment in thousands of dollars taken from the 1967 *Census of Business.*

S = The average sentence served by inmates released from State and Federal Institutes who had been charged with either robbery, burglary, or larceny over \$50. This is state wide.

I = Community population, in thousands, taken from the estimates of 1968 population made by Rand McNally and published in their *Commercial Atlas and Marketing Guide.*

NW = The percent of the city population which was nonwhite in 1960, taken from the 1960 *Census of Population.*

SY = Mean school years completed by residents of the community in 1960 taken from the 1960 *Census of Population.*

D = Population density, persons per square mile, for the community taken from the 1960 *Census of Population.*

pected loss of utility is less than the utility of the expected loss, and that the cost of arrest is large, it follows that the change in the expected loss of utility will be greater for a 1 percent increase in $r(A)$ than for a 1 percent increase in the cost of punishment. This implies that more crimes will be prevented by increasing $r(A)$ than by increasing the cost of punishment or that the elasticity of N/I with respect to $r(A)$ should be greater than with respect to S, which is our measure of the cost of punishment.

The coefficient of E, retail sales per establishment, is positive in three of the four equations in Table 1. Retail sales per establishment is admittedly a very crude measure of the gain to criminal activity, a statement which is borne out by the low values of the t-statistic.

The only result of the analysis which ap-

pears to be in conflict with the theory is the coefficient for income, which we find to be positive, whereas a negative coefficient is anticipated. If it is true, as previously suggested, that *GW* is a measure of the gain to both legal and illegal activity, the coefficient of income could be either positive or negative.

To test our theory further, we ran regressions employing two additional variables, the labor force unemployment rate, *UE*, and the percent of families with incomes below $3,000, *PCBT*, for which we would expect positive coefficients. As seen in Table 2, the coefficients for *UE* are all positive while the coefficients for *PCBT*, however, are mixed.

Let the two roles that income plays in our model be designated as the "gain effect," i.e., as a measure of the gain from crime, and the "need effect," i.e., as a measure of the gain from legal activity. The results presented in Table 2 provide some evidence

$$+ \underset{(4.156)^*}{.137\,\ln NW} + \underset{(1.580)^*}{.826\,\ln SY} + \underset{(.015)}{.002\,\ln D} + \underset{(2.822)^*}{.343\,\ln UE} \qquad R^2 = .637$$

4) $$\ln N/I = -1.65 - \underset{(-3.857)^*}{.368\,\ln r(A)} - \underset{(-.981)}{.186\,\ln S} + \underset{(.850)}{.220\,\ln E} + \underset{(1.452)^*}{.184\,\ln I} + \underset{(4.161)^*}{.137\,\ln NW}$$
$$+ \underset{(1.644)^*}{.857\,\ln SY} + \underset{(.040)}{.004\,\ln D} + \underset{(2.772)^*}{.336\,\ln UE} \qquad R^2 = .629$$

5) $$\ln N/I = -1.47 - \underset{(-3.608)^*}{.356\,\ln r(A)} - \underset{(-1.051)}{.204\,\ln S} + \underset{(.347)}{.101\,\ln E} + \underset{(.927)}{.273\,\ln GW} + \underset{(1.453)^*}{.189\,\ln I}$$
$$+ \underset{(2.964)^*}{.130\,\ln NW} + \underset{(1.546)^*}{.820\,\ln SY} + \underset{(.006)}{.001\,\ln D} + \underset{(2.794)^*}{.347\,\ln UE} + \underset{(.240)}{.383\,\ln PCBT} \qquad R^2 = .638$$

6) $$\ln N/I = -1.49 - \underset{(-3.709)^*}{.364\,\ln r(A)} - \underset{(-.956)}{.184\,\ln S} + \underset{(.773)}{.207\,\ln E} + \underset{(1.398)^*}{.181\,\ln I} + \underset{(3.432)^*}{.142\,\ln NW}$$
$$+ \underset{(1.627)^*}{.858\,\ln SY} + \underset{(.043)}{.005\,\ln D} + \underset{(2.708)^*}{.334\,\ln UE} - \underset{(-.237)}{.033\,\ln PCBT} \qquad R^2 = .629$$

* Significant at 10 percent level with a one-tailed test.

[a] In addition to the variables defined in Table 1, Table 2 includes:

PCBT = Percent of the families in the community who had incomes below $3,000 in 1959 taken from the 1960 *Census of Population*.

UE = The labor force unemployment rate in 1968 generated from data published by the Bureau of Labor Statistics.

The sample size for both regressions is 53, as is reported in the text.

that the coefficient of income is picking up the gain effect. When *PCBT* and/or *UE* are used with *GW*, part of the need effect should be removed from the coefficient of *GW*, resulting in a larger coefficient for *GW* which we find when comparing equation 1) of Table 1 with the equations in Table 2. Likewise, when *GW* is removed from the equation, the coefficients for *UE* and *PCBT* fall, since they are now picking up the gain effect. This would also explain two of the negative coefficients for *PCBT*.

We also note that the coefficient for *E* moves in the opposite direction of the movement of the coefficient of *GW*, providing further evidence for our explanation of the positive coefficient for income.

IV. Conclusions

Following the lead of Becker and Fleisher, we have postulated an economic theory of property crime. Employing a Von Neumann-Morgenstern utility function we developed a model in which an individual must allocate his time between legal and illegal activities so as to maximize expected utility. We tested the model by running regressions on a cross-sectional sample of communities.

The empirical results give at least tentative credence to our hypothesis. We find that an increase in the probability of arrest and conviction and an increase in the cost of crime (punishment) both result in a decrease in the number of major property crimes committed.

Given our results, further work in this area does not appear to be out of order, particularly more sophisticated work employing better data.

A Skeptical Note on "The Optimality" of Wage Subsidy Programs

By IRWIN GARFINKEL*

In "Optimal Mechanisms for Income Transfers," a recent paper in this *Review*, Richard Zeckhauser purports to demonstrate the welfare superiority of wage subsidies to negative income tax programs. He assumes that taxpayers derive utility both from increases in the incomes and from increases in the hours worked of poor people. In his simple model of a single beneficiary and a single taxpayer, he shows that wage subsidy (*WS*) programs are less leisure inducing than equally costly negative income tax (*NIT*) programs, and are, therefore, Pareto superior.

There are at least three reasons for being skeptical. First, Zeckhauser and others[1] notwithstanding, there is no theoretical basis for concluding that pure *WS* programs involve less static work disincentive than pure *NIT* programs.[2] Second, Zeckhauser ignores the fact that the cost of *WS* and *NIT* programs depends not only upon the differential static work incentive effects of the two programs but as well upon the differential human investment incentive effects. Third, he also ignores the differential effects of demand on the costs of *WS* and *NIT* programs. In this note I show that: 1) the analytical confusion about the work incentive effects of *WS* and *NIT* programs arises from attempting to generalize from the single beneficiary case to the many beneficiaries case;[3] 2) the human investment incentive effects of *NIT* programs could possibly be superior to those of *WS* programs; and 3) the explicit introduction of demand into the analysis may also eliminate the alleged welfare superiority of *WS* programs.

Before proceeding with the analysis, it will be useful to describe algebraically the alternative economic opportunities which are available to individuals if there is no program, a *WS* program, or an *NIT* program. The budget constraints of individuals with income only from earnings, income from earnings plus an *NIT* grant, and income from earnings plus a *WS* grant are described algebraically below:

$$(1)\quad Y = HW$$

$$(2)\quad Y = G + (1 - m)HW \qquad \text{for } Y \leq \frac{G}{m}\text{; otherwise}$$
$$Y = HW,$$

$$(3)\quad Y = [g + (1 - n)W]H \qquad \text{for } W \leq \frac{g}{n}\text{; otherwise}$$
$$Y = HW,$$

* The research reported here was supported by funds granted to the Institute for Research on Poverty at the University of Wisconsin by the Office of Economic Opportunity pursuant to the provisions of the Economic Opportunity Act of 1964. I wish to acknowledge the helpful comments and suggestions of Michael Barth, Glen Cain, Edward N. Gramlich, Stanley Masters, Larry Orr, and Harold Watts. The conclusions are solely my responsibility.

[1] Jonathan Kesselman concludes, "the wage subsidy offers less static disincentive to work than any income subsidy (that is, *NIT*) plans yet developed" (p. 276). Michael Barth and David Greenberg recognize in a footnote that if labor supply curves are backward bending, the above conclusion may not hold, yet in the text of their paper they state their agreement with the above conclusion. Zeckhauser and Peter Schuck simply assert that a *WS* has superior incentive effects.

[2] Barth and Greenberg demonstrate that mixed *WS-NIT* systems in which individuals may receive subsidies simultaneously from both a *WS* and *NIT* program may induce greater labor supply reductions than pure *NIT* systems. I demonstrated in my discussion paper that the kind of self-categorizing mixed *WS-NIT* system advocated by Zeckhauser and Schuck may also induce greater labor supply reductions than pure *NIT* systems. Unlike the pure *WS* systems discussed in the text, either kind of mixed *WS-NIT* program could induce greater labor supply reductions than pure *NIT* systems even if no beneficiaries had backward bending labor supply curves.

[3] Richard Musgrave clarified a similar confusion in the analysis of the differential work incentive effects of a proportional and progressive income tax by distinguishing between the single taxpayer and many taxpayers cases.

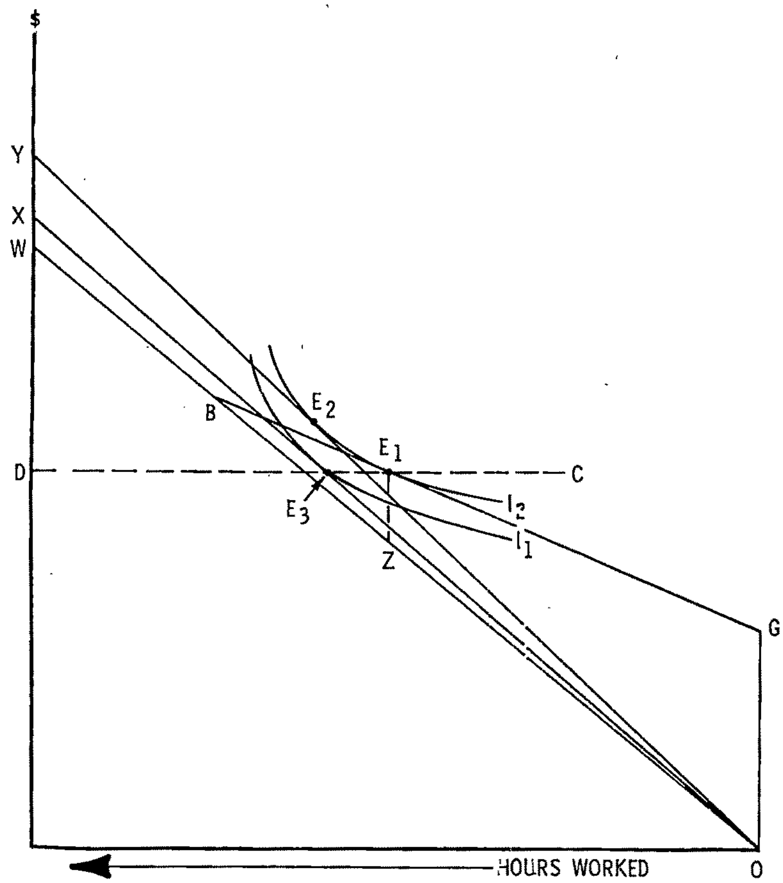

FIGURE 1. WORK INCENTIVE EFFECTS OF *WS* AND *NIT* PROGRAMS: SINGLE BENEFICIARY CASE

where Y = net income, H = hours worked, W = hourly wage rate, G = guarantee in the negative income tax (subsidy for a given family size when other income is equal to zero), m = marginal tax rate $(0<m<1)$ in the negative income tax program, g = the guaranteed wage rate (the minimum hourly wage rate the government will pay anyone irrespective of his market wage rate), and n = the marginal tax rate $(0<n<1)$ on wages in a wage subsidy. Individuals with earnings above G/m, the break-even level of income in the negative income tax program, receive no income subsidy. Individuals with wage rates above g/n, the break-even wage rate in the wage subsidy, receive no wage subsidy.

I. Work Incentive Effects

Single Beneficiary Case

It is easy to show given the conventional partial equilibrium assumptions that a single individual will work more under a *WS* than an *NIT* program if either his post-subsidy welfare, or his postsubsidy income, or his subsidy, is the same under the two programs. These three cases are demonstrated below with the aid of Figure 1.

Hours of work are measured from right to left along the horizontal axis and income along the vertical axis. It is assumed that initially all income is earned. The original budget constraint is given by the wage line *OW*. An *NIT* with a guarantee of *OG* dollars

results in a new budget constraint $OGBW$. Assume the new equilibrium lies along BG at a point such as E_1 where I_2 is tangent to GB. (The initial equilibrium is unspecified here except that it lies to the left of E_1 along OW.) Now consider a WS that would leave the individual indifferent between E_1 and a new equilibrium such as E_2. A WS pivots the old budget constraint or wage line OW, upwards from 0, resulting in a new wage line such as OY. The line OY must be steeper than GB since the WS increases the net wage while the NIT decreases the net wage. Consequently, given indifference curves with diminishing marginal rate of substitution, E_2 must lie to the left of E_1.

Now consider a WS that would leave the individual with the same income as the NIT program. Equilibrium must lie along the line DC, which passes through E_1 and which is parallel to the horizontal axis. Given indifference curves with diminishing marginal utility of leisure, only indifference curves which intersect DC to the left of E_1, will be steeper than the one at E_1. Since the new WS line must be steeper than GBW, equilibrium must lie to the left of E_1, at a point like E_3, where OX is tangent to I_1. The individual will work harder and be worse off under the wage subsidy.

Finally, it is now easy to see that if two WS and NIT programs are equally costly the former must lead to greater labor supply. The cost of the NIT program in the partial equilibrium framework of Figure 1 is equal to E_1Z, the net subsidy to the beneficiary. (The actual costs in general equilibrium will depend on the elasticity of the demand for labor. See Section III below.) Given indifference curves with diminishing marginal rates of substitution, equilibria on a WS budget line which entail a net subsidy as large as E_1Z must lie to the left of E_1.

Two (and Many) Beneficiaries Case

The major problem with the foregoing analysis is that while WS and NIT programs can be constructed so as to hold constant one individual's welfare or income, it is impossible to construct them in such a fashion that all individuals' welfare or income is held constant—unless wages and preferences of all individuals are identical. This point is extremely important, because it means that we cannot generalize from the single beneficiary case to the many beneficiaries case.

This is readily demonstrated by reference to Figure 2, which depicts the indifference curves of B_1, and of an additional potential WS or NIT beneficiary (B_2). While the wage rates of B_1 and B_2 are identical, their tastes differ. At low levels of income, B_2 has a much stronger preference for income vis-à-vis leisure than does B_1. Hence B_2's initial presubsidy equilibrium is at $E_0^{B_2}$ while B_1's initial equilibrium is at $E_0^{B_1}$.

The postsubsidy welfare of B_1 would be identical under the WS program which pivoted his budget constraint from OW to OY and the NIT program which shifted his budget constraint from OE to $OGBW$. But while B_2 would choose not to get any positive subsidy from the NIT program, he would necessarily benefit from the WS program. Thus while the NIT and WS programs hold B_1's postsubsidy welfare constant, they do not hold B_2's postsubsidy welfare constant. And, given differences in tastes and wage rates, unless special plans for every individual are devised, it is impossible to construct WS and NIT programs that would hold constant all individual potential beneficiaries' postsubsidy income or welfare.

Indeed Zeckhauser's simple model breaks down in the many beneficiaries case. For equally costly WS and NIT programs would lead in general to different distributions of welfare among potential beneficiaries. Without interpersonal utility comparisons, it is impossible to ascertain whether WS or NIT programs are Pareto superior.

More important perhaps, it is now easy to show that one cannot say a priori that WS programs must entail less static disincentive than NIT programs. As depicted in Figure 2, B_1 works more if the WS rather than the NIT program is enacted. But B_2 works less. Moreover as depicted, the magnitude of B_2's differential response, ab, exceeds, cd, that of B_1's. This constitutes a theoretical proof by counterexample that not all WS

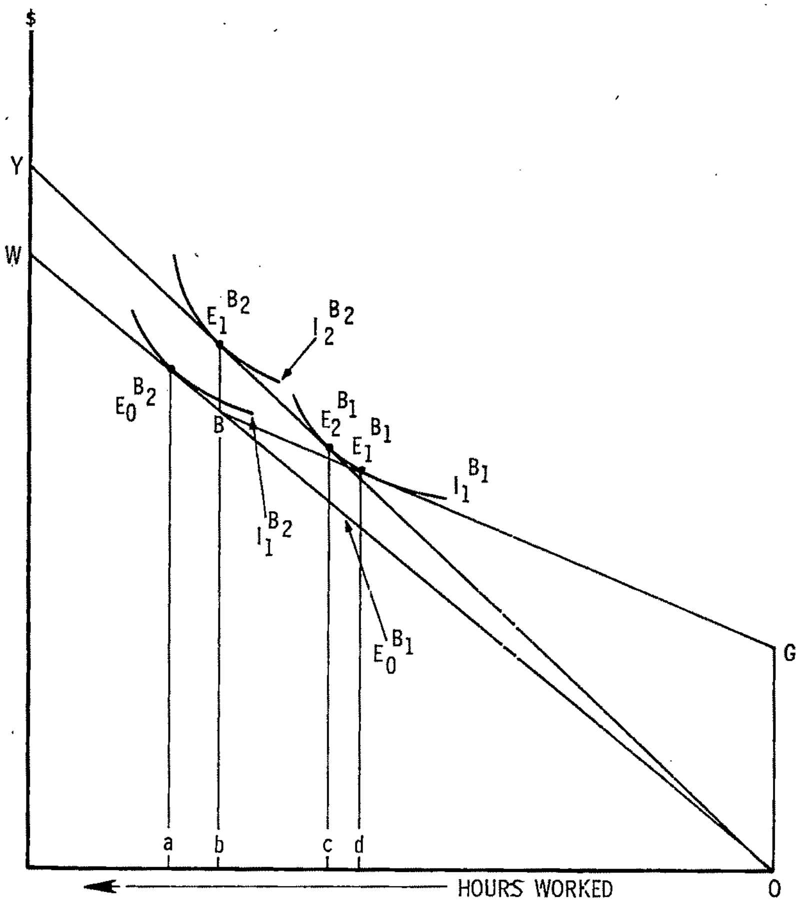

FIGURE 2. WORK INCENTIVE EFFECTS OF *WS* AND *NIT* PROGRAMS
TWO BENEFICIARIES CASE

programs entail less static disincentive than all *NIT* programs.

Note that as illustrated in Figure 2, the sum of the subsidies to B_1 and B_2 is greater in the *WS* than in the *NIT* program. Yet, it is easy to construct a plausible example in which the aggregate cost of the two programs is identical and the *WS* still entails more work disincentive. Imagine a third individual, B_3, whose wage rate and tastes are identical to B_2's, but whose work activity is restricted sufficiently by illness so that his subsidy from the *NIT* program would exceed his subsidy from the *WS* program by an amount which would equate the sum of the subsidies to B_1, B_2, and B_3 from the *WS* and *NIT* programs. Since B_3's labor supply would be determined by his health constraint and thereby is unaffected by either the *WS* or *NIT* program, we now have an example where an equally costly *WS* program entails more work disincentive than an *NIT* program.

My proof by counterexample depends upon a particular configuration of tastes, wage rates, and health status. The critical assumption is that some low wage individuals like B_2 have backward bending supply curves, yet refuse to participate in an *NIT* program because doing so would entail a reduction in their income.[4] This assumption

[4] If no individuals have backward bending supply curves, a pure *WS* system must necessarily entail less static work disincentive than a pure *NIT* system. For the *WS* will always be work inducing while the *NIT* will be leisure inducing provided leisure is a normal good.

and the others are, I believe, quite plausible. But the important point is that whether or not *WS* programs will entail less work disincentives than equally costly *NIT* programs is an empirical rather than a theoretical issue.

II. Human Investment Incentive Effects

The equilibrium condition for a utility maximizing individual who is considering a human investment decision is[5]

$$\frac{B}{(1+r)^t} = C \tag{4}$$

where B = benefit, C = cost, r = discount rate, and t = time period. That is, the individual will undertake the investment as long as the present value of the benefits exceeds the present value of the costs, where for simplicity all the costs are assumed to take place in the initial period t_0 and all of the benefits in period t_1. Let

$$B = H(W_T - W_0)_{t_1} + (NPB_T - NPB_0)_{t_1} \tag{5}$$

$$C = (H_0W_0 - H_TW_T)_{t_0} + D_{t_0} \tag{6}$$

where W = the wage rate, NPB = nonpecuniary benefits, H = hours worked, D = direct costs, and the subscripts T and 0 indicate respectively, with and without training. Note that in period t_0, H_T and W_T refer to hours and wage rates during training, while in t_1 they refer to hours and wage rates subsequent to training. Substituting (5) and (6) into (4) yields

$$\frac{H(W_T - W_0)_{t_1} + (NPB_T - NPB_0)_{t_1}}{(1+r)^t} = (H_0W_0 - H_TW_T)_{t_0} + D_{t_0} \tag{7}$$

On-the-job investment or training (*OJT*) is defined as a human investment which entails a reduction in W_0. Off-the-job investment is defined as an investment that entails a reduction in H_0.[6]

Enactment of either a *WS* or an *NIT* program would increase incentives to obtain *OJT*.[7] Consider first the effect of a *WS* program. If both the pretraining wage rate in the absence of training, W_0, and the posttraining wage rate, W_T, are below the break-even wage rate, and nonpecuniary benefits do not increase as a result of training, the *WS* program will reduce benefits by n percent. But enactment of the *WS* program would also reduce the opportunity costs, $H(W_0-W_T)_{t_0}$, of *OJT* by n percent. If we assume there are no direct costs to *OJT*,[8] therefore, the enactment of a *WS* program would not reduce the incentives of any workers to obtain *OJT*. Moreover, if either the pretraining wage rate in the absence of training or the posttraining wage rate are above the break-even wage rate, or if nonpecuniary benefits increase as a result of training, the *WS* program will reduce benefits by less than n percent and thereby increase the incentive to obtain *OJT*. Similarly enactment of an *NIT* will reduce the costs of *OJT* by m percent and the benefits by up to, but often by less than, m percent. Without knowledge about program parameters and individual preferences it is impossible to specify whether enactment of a *WS* or an *NIT* would lead to the greatest increase in incentives to obtain *OJT*.

A *WS*, however, would definitely provide greater *disincentives* than an *NIT* to obtain off-the-job human investment. The benefits of such an investment would again be reduced by up to n and m percent, respectively by enactment of either a *WS* or an *NIT* program. But the enactment of any *WS* would also increase the cost of off-the-job human investment by increasing the value of fore-

[5] I ignore the problems created by lumpiness of both costs and benefits.

[6] Although off-the-job investment need not entail reductions in hours worked, nearly all forms of such investment do involve reductions in hours.

[7] If there are no costs to training, the rational individual will always undertake the training so long as the benefits are greater than zero. The mere process of working may entail training. Whether this is true of the jobs held by poor workers is open to question. But if this were the case and if an *NIT* were more leisure inducing than a *WS* in the aggregate, it could be argued that more on-the-job training would take place if a *WS* rather than an *NIT* program were enacted because workers would be on the job more of the time in the former program.

[8] If the direct costs are greater than zero, the total costs would be reduced by less than n percent and there might actually be a disincentive.

gone earnings. In contrast, enactment of an *NIT* would never increase, and in many cases would reduce by up to *m* percent, the costs of off-the-job human investment. Thus, even if the enactment of an *NIT* program would discourage such investment because it reduced the costs of an investment by a smaller percentage than the benefits, the disincentives would be much smaller than those engendered by the enactment of a *WS* program.

Given the larger off-the-job human investment incentive effects of a *WS*, it is possible that a *WS* which appears to cost the same as an *NIT* when only their static work incentive effects are considered, may actually be more costly. Again, whether the overall human investment incentives effects of an *NIT* are superior to those of a *WS* is an empirical question which would depend upon such factors as program parameters, tastes, and the relative payoffs to poor workers of on- and off-the-job human investments.[9]

III. General Equilibrium Effects

Finally, it is impossible to analyze the benefits to beneficiaries or the costs to taxpayers of *WS* and *NIT* programs within the partial equilibrium framework employed by Zeckhauser.[10] If *WS* programs do lead to increases in the labor supply of poor people, market wage rates will fall, subsidy inclusive wage rates will fall, and the cost of the program will increase unless the demand for labor is perfectly elastic. The greater is the inelasticity of demand, the smaller are the benefits to the poor and the larger are the costs to the taxpayer of *WS* programs. Since on the other hand *NIT* programs must decrease the supply of labor, the more inelastic is the demand for labor, the larger are the increases in beneficiary wage rates and the smaller are the *NIT* program costs to the taxpayer. (Of course, *WS* programs could also lead to such results if in the aggregate like *NIT* programs, they turn out to be leisure inducing.) If the demand for labor is as inelastic as many studies suggest,[11] even with highly inelastic labor supply curves, very costly *WS* programs might lead to relatively small increases in the total incomes of the poor. The welfare superiority of *WS* to *NIT* programs in these circumstances is doubtful. In any case, it is clear that one cannot compare the welfare effects of *WS* and *NIT* programs without considering the elasticity of the demand for labor. The partial equilibrium costs and benefits of *WS* and *NIT* programs identified by Zeckhauser will only be equal to the general equilibrium costs and benefits if the demand for the labor of the poor is perfectly elastic.

I conclude by simply noting that since Zeckhauser's "demonstration" of the optimality of wage subsidy programs depends explicitly on the alleged superior work incentive effects of *WS* vis-à-vis *NIT* programs, and implicitly on the assumptions that the programs have no differential human investment incentive effects, and that the demand for labor is perfectly elastic, the case for the optimality of wage subsidy programs is open to serious question.

[9] While the returns to *OJT* appear in general to be large, many poor workers are apparently poor precisely because their jobs have very little *OJT* component to them. On the other hand, the returns to poor workers from their current off-the-job human investments may also be small. It is clear that the differential human investment incentive effects on the poor of *WS* and *NIT* programs is a very complicated empirical question.

[10] I am indebted to Edward Gramlich and Michael Barth for calling my attention to the importance of the demand for labor in evaluating *WS* programs.

[11] See S. W. Black and H. H. Kelejian, especially fn. 5, p. 721, for a brief summary of estimates of the elasticity of demand for all labor. Their own estimate is .364. Two as yet unpublished studies by Edward Gramlich and Ernst Berndt and Laurits Christensen which attempt to estimate the elasticity of substitution for low-wage labor use different data sources and methodologies and derive very different estimates. Gramlich estimates that demand is highly inelastic while Berndt and Christensen estimate that demand is highly elastic.

Optimal Mechanisms for Income Transfer: Note

By ROBERT E. SCHLENKER*

In a recent article in this *Review*, Richard Zeckhauser examines the subject of income transfer and concludes that a wage subsidy scheme (WS) is superior to a negative income tax plan (NIT). Zeckhauser's results are derived from a model in which a single representative poor man faces a single, fixed wage rate. The purpose of this comment is to extend Zeckhauser's discussion by comparing the two plans in a setting of many potential recipients, some unemployable and the rest facing different wages rates. When this is done, the superiority of the WS approach over the NIT does not appear quite as clear-cut as suggested in Zeckhauser's article.

The many-recipient setting requires two modifications in Zeckhauser's WS plan. First, a positive income floor is needed to cover those who are unemployable or who can work only a small number of hours. Under the scheme presented in Zeckhauser's article, with a negative basic stipend, such individuals would actually be taxed to subsidize the more affluent poor. Second, the subsidy must vary with the wage rate in such a way as to provide a smooth transition from subsidized and unsubsidized rates. The NIT deals with both those problems by providing an income floor and a break-even earnings level at which the subsidy ceases. Zeckhauser is also well aware of the problems and, with Peter Schuck, has suggested a realistic operational WS plan in another writing. The structure of that plan forms the basis for our subsequent discussion.

I. An Operational Wage Subsidy Plan

Zeckhauser and Schuck propose a two-plan approach as illustrative of a more general multiple-plan approach. One plan provides a relatively large basic stipend and places a high marginal tax rate on earnings; the other plan combines a small basic stipend with a wage subsidy (or negative tax rate on earnings). The subsidy varies with the wage rate so as to make up half the difference between the actual wage rate and \$3 per hour. The choice of plan would be left to each recipient. The two-plan approach thus deals with the situation of many recipients by providing an income floor and a wage rate subsidy which declines as the wage rate increases.

Assuming the poor are economically rational, those with low potential earnings would choose the plan with the high basic grant and high tax rate, while those with higher potential earnings would choose the wage subsidy option. Assuming, for simplicity, that the high stipend, high tax rate option incorporates a 100 percent tax rate, a client's income would then be represented by:

$$(1) \quad y = [w + b(w_0 - w)]h, \qquad \text{for } y > g, \quad \text{and} \quad w < w_0,$$

and

$$(2) \qquad y = g \text{ otherwise}$$

In these equations, y is the total income of the recipient g is the income floor (the basic stipend under the high stipend-high tax rate plan); w_0 is the break-even wage rate, or the rate at which the wage subsidy ceases; b is the fraction of the difference between the actual wage rate and the break-even wage rate which is made up by the subsidy; w is the actual wage rate; and h represents the actual number of hours worked. In Zeckhauser and Schuck, $b = .5$ and $w_0 = \$3$. Equation (1) is easily derived (see also the article by Jonathan Kesselman) from the fact that the subsidy, $y - wh$ (i.e., total income minus earned income), is designed to make up the

* Senior staff member of Inter Study, a policy research organization in Minneapolis, Minnesota. Helpful comments were received from a reviewer.

fraction, b, of the gap between w_0 and w. Therefore, $y-wh$ equals $b(w_0-w)h$ for $w<w_0$ and for all h, and solving for y yields equation (1).[1]

II. A Comparative Negative Income Tax Plan

For our purposes, the most useful way to compare the WS and NIT income transfer approaches is to provide them with identical boundary points on the range of earnings subsidized. That is, we postulate the same income floor and the same break-even point for each plan.

Because the break-even condition is defined in terms of earnings for the NIT and in terms of the wage rate for the WS, an additional specification is needed to link the two together. We do this by specifying h_0 as a reasonable maximum for the number of hours worked (such as 2,000 hours per year), and stating the condition, $w_0h_0=y_0$, where y_0 is the break-even earnings level under the NIT. If h_0 is a realistic maximum for h, then neither plan will subsidize earnings above y_0.

With these specifications, the equation for total income under the simplest form of a comparative NIT is:

$$(3) \qquad y = g + ewh$$

where g is again the income floor and e is a constant fraction determined by the income floor and break-even point as $(y_0-g)/y_0$. While the WS and the NIT plans we have specified will have identical income floors and identical break-even earnings levels, within the subsidized earnings range, the plans will be quite different.

[1] Equation (1) is noticeably different from the formulation given in Zeckhauser's (1971) model because of the necessity of dealing with different wage rates. Zeckhauser's WS equation is $y=s+hw(1-t)$, where s is the basic stipend and t is the marginal tax rate; both s and t are negative. In the multiple wage rate case, we must require that wage rates less than the break-even rate, w_0, although subsidized, result in effective wage rates which are less than w_0 and rise toward w_0 as w rises toward w_0. Therefore $w(1-t)$ must be positive, less than w_0, and rise toward w_0 as w rises toward w_0. Specifically, at $w=w_0$, t must equal 0. Also, at $w=w_0$, the income subsidy must vanish and $y=w_0h=s+hw_0(1-t)$. With $t=0$, this implies that $s=0$. With $s=0$ and $t=-b(w_0/w-1)$, with $0<b<1$, the desired conditions are met and equation (1) results.

III. Taxes and Subsidies Under the Two Plans

Under both plans, the recipient can increase his income in only two ways: increasing hours worked or the wage rate. The effects of an increase in hours worked will be examined first. From equations (1)–(3), partial differentiation of y with respect to h yields:

$$(4) \qquad WS\colon \frac{\partial y}{\partial h} = w + b(w_0 - w) \quad \text{for } y > g$$
$$= 0 \text{ otherwise}$$
$$NIT\colon \frac{\partial y}{\partial h} = ew$$

Since $w_0>w$ and $e<1$, $w+b(w_0-w)>w$ and $ew<w$. Thus, as expected, the NIT taxes increases in hours worked while the WS subsidizes such increases if $y>g$. However, if $y\leq g$, the WS plan levies a ***higher*** tax rate on increases in hours worked than does the NIT. The need for an income floor thus significantly affects the relative merits of the WS and NIT plans, and the role of the floor deserves further consideration.

The Role of the Income Floor

With an income floor, low wage employment would be discouraged under a WS plan, because a 100 percent tax rate would apply until after-transfer income rose above g. A lower tax rate would apply to the NIT. Thus, some persons could be expected to work under NIT who would not work under WS. For such persons, the NIT would yield higher total incomes and lower transfer costs than would the WS. (The transfer cost under NIT is $g-(1-e)wh$; under WS it is g for such persons.)

To encourage more employment at low wage rates, a high value of b could be utilized. The only restriction on b under WS is that it be between 0 and 1. To encourage employment, the after-transfer income from employment would have to be greater than the income floor by a significant amount even at low earnings levels. From equations (1) and (2), this would require that $[w+b(w_0-w)]h>g$ even for low wage rates and hours worked; the greater the value of b, the lower

the values of w and h at which the inequality would hold. How large a value of b is required? This is an empirical question on which we have no information but the examples in Table 1 provide some insights.

The table indicates the number of hours of work required before the income from work with a wage subsidy exceeds the value of the income floor. The hours are calculated for different wage rates, different values of b, and different income floors. The general point is that a relatively high value of b may be necessary in order to encourage employment at low wage rates. For example, if 2,000 hours represents full-time work (on an annual basis) and \$3,000 is the floor, at least half-time work is required under all values of b before work income exceeds the floor for wage rates less than \$2. If the floor is \$2,000 the number of hours required is smaller. In either case, the greater the value of b, the lower the required number of hours.

Table 1—Minimum Hours of Work Necessary Under *WS* for Income to Exceed Floor

	$b=.25$	$b=.50$	$b=.75$	$b=.90$
Case 1. $g=3,000$, $y_0=6,000$, $w_0=3$, $e=.5$				
$w=1$	2000	1500	1200	1071
2	1333	1200	1091	1034
Case 2. $g=2,000$, $y_0=6,000$, $w_0=3$, $e=.67$				
$w=1$	1333	1000	800	714
2	889	800	727	690

A high value of b may thus be required if low-wage employment is to be encouraged under a *WS* plan. There is a tradeoff involved, however, between increasing b and increasing the incentive for recipients to obtain wage rate increases, as discussed below.

The Wage Rate Tax

The second way the recipient can increase his income is by obtaining a wage rate increase. While major concern is usually with hours worked (see Zeckhauser), the tax on wage rate increases is not a trivial issue. For instance, under a *WS* plan, at a given wage rate, the transfer cost for a recipient can only be reduced if the recipient reduces his hours of work. The current welfare reform debate suggests that such action would be frowned upon by the nonpoor (even if program costs were thereby reduced). The only acceptable way to reduce costs would then be via wage rate increases. The emphasis on manpower programs in welfare reform proposals indicates the public attractiveness of programs which promise to increase the productivity of the poor. At the same time, the notable lack of success demonstrated by such programs in the past indicates that obtaining wage rate increases is not costless for either recipient or society. Taxing wage rate increases, by adversely affecting recipient incentives to obtain such increases, can only intensify the problem.

Both *WS* and *NIT* place a tax on wage rate increases. The relevant effective wage rates were given in equation (4) above. The change in the effective wage rate resulting from a change in the actual wage rate can be found by differentiation of (4) with respect to w:

$$(5)\qquad WS:\ \frac{d}{dw}\left(\frac{\partial y}{\partial h}\right) = 1 - b \quad \text{for } y > g$$
$$= 0 \quad \text{otherwise}$$
$$NIT: \qquad = e$$

The tax rate on wage rate increases is 1 minus the effective wage rate increases given in (5). Thus, the tax rate on wage rate increases is b under *WS* and $1-e$ under *NIT*. Under *WS* there is therefore a tradeoff between the size of the wage rate subsidy and the tax on wage rate increases. The greater b, the greater are both the subsidy and the tax.

In addition, when the *WS* and *NIT* are compared in terms of the tax on wage rate increases, it is evident that the value of b may have to be greater than $1-e$ in order to encourage work at the lower end of the earnings range.[2] This is illustrated in Table 1.

[2] Graphically, the relation between b and $1-e$ can be shown as follows. On a diagram with h measured along the horizontal axis, equation (1) of the *WS* plan would be a straight line beginning at the origin and rising with slope $w+b(w_0-w)$. The *NIT* plan line would begin at height g on the vertical axis and rise with a lower slope of ew. Since $e=(y_0-g)/y_0$ and $h_0w_0=y_0$, the two lines

In Case 1, b would be greater than $1-e$ if b were greater than .5; in Case 2, this would occur if b were greater than .33. In other words, an operational *WS* plan may result in a higher tax rate on wage rate increases than would be present under a comparable *NIT* plan.

Whether or not a higher *WS* wage rate tax means a recipient will be less likely under *WS* than *NIT* to seek a given wage rate increase depends, of course, not on the increase in the effective wage rate but on the increase in income. If the *WS* leads to a greater equilibrium number of hours worked at all wage rates, then the *income* increase resulting from a given wage rate increase might still be greater under *WS* than under *NIT*. The size of the incentive to increase wage rates under the two plans, the costs of obtaining the increases, and the difference in response under the two plans are obviously subjects for empirical investigation. The negative income tax experiments currently underway will, unfortunately, provide answers only for the *NIT* approach.

would intersect at

$$h = [y_0(1 - e)]/[w(1 - e - b) + bw_0]$$

where we have replaced g by $y_0(1-e)$. It can then be shown that for $w<w_0$ the intersection will occur at $h=h_0$ only if $b=1-e$. Similarly, for $w<w_0$ the intersection will occur at $h<h_0$ only if $b>1-e$. Comparisons of the two plans at the same number of hours worked are, of course, inappropriate, since a major objective of the *WS* is to lead to a greater number of hours worked than the *NIT*. The point of this calculation is only to emphasize the fact that if the *WS* is to lead to significantly greater income possibilities than the *NIT*, it may be necessary to levy a greater tax on wage rate increases under the *WS*.

IV. Conclusions

These remarks are not intended as an argument against the wage subsidy concept, for the idea has considerable merit. Rather, my major thrust is that a complete appraisal of alternative income transfer mechanisms must include considerations in addition to those raised by Zeckhauser. To reiterate the main points: an operational wage subsidy plan requires an income floor and a wage rate subsidy which declines as the wage rate increases. The existence of a floor may require high subsidies of low wage rates in order to encourage any work at these levels; the negative income tax may thus lead to more work by those facing low wage rates than would the wage subsidy. High subsidy rates at low wage rates, in turn, may result in a higher tax rate on wage rate increases than would exist under a negative income tax plan with the same income floor and break-even earnings level. Finally, the magnitude of and response to these various incentives are sufficiently unclear as to call for extensive empirical investigation.

On Terms of Foreign Borrowing

By PRANAB K. BARDHAN*

The theoretical literature on terms of foreign borrowing is rather narrow in the range of issues analyzed. Much of the recent literature is on an elaboration of the standard "optimum tariff" argument to the case where services of capital are internationally purchased.[1] It is now well-known that a borrowing country, if it is an important borrower in the international capital market, may gain by restricting its international borrowing; depending on the relevant elasticities, one can easily work out the optimum terms (or the interest rate) at which borrowing should be done so that the monopoly power (strictly, monopsony power in the purchase of capital services) in the international capital market is fully utilized.

For many borrowing countries, particularly in the underdeveloped world, the relevance of this analysis is, however, limited. These countries, taken individually, are often small borrowers in the international capital market and the task of setting on the national level the optimum terms of borrowing on the basis of their monopsony or oligopsony power is not particularly relevant. But a more significant limitation is that the whole analysis is static and ignores important time dimensions involved in problems of capital borrowing. The present paper concentrates on one such dimension.

The terms of a foreign loan involve not merely the interest rate but also a maturity period by which time the loan is to be paid back. In the real world a borrowing country is often confronted with a choice among alternative loan packages with varying rates of interest and lengths of maturity period. From the point of view of the long-run benefits of the borrowing country, how should one choose between a loan with, say, 5 percent rate of interest and a maturity period of 20 years and another loan with a higher, say, 7 percent rate of interest but a longer maturity period of, say, 30 years? Or, to put it in other words, in the long run is a rise in the interest rate on the foreign loan by a certain percentage costlier than a given shortening of the maturity period? This is an important practical problem in loan negotiations, and the existing theoretical literature on foreign borrowing does not throw much light on it.[2] The present paper tries to answer the problem in terms of a very simple dynamic model.

I take a Harrod-Domar growth model with its drastically simplifying assumptions of a constant capital-output ratio and the ratio of savings to national income. There is only one commodity, and problems of trade with incomplete specialization are ignored. The foreign loan under consideration is a once-for-all addition to the capital stock of the country. For simplification again, all capital is assumed to last forever, but the foreign loan has to be amortized in equal annual installments. I also ignore the gestation lag between availability of capital and its yield of output.

National income, Y, is given by

$$(1) \qquad Y = a(K + L) - iL\left(1 - \frac{t}{T}\right)$$

where a is the output-capital ratio, K is the domestically owned capital stock, L is the given amount of foreign loan, T is the maturity period of the loan, t is time, and i is the interest rate. The second term on the right-hand side of (1) is the drain on national income due to interest payments on the foreign loan.

* Professor of economics, Indian Statistical Institute, New Delhi. In formulation as well as analysis of the problem in this paper, I have benefitted from discussions with G. Arsenis and V. K. Sastry. All errors are, of course, mine alone.

[1] See, for example, Murray Kemp, ch. 13, and references cited there.

[2] The only two references in the theoretical literature where I have seen a brief mention of the problem are Abdul Quayum, p. 369, and Goran Ohlin, pp. 49–50.

Assuming that savings form a constant fraction, s, of national income and are instantaneously invested, over the loan period capital accumulation is given by

$$\frac{dK}{dt} = sY - \frac{L}{T} \tag{2}$$

where the second term on the right-hand side of (2) is the annual amortization payment. Integrating the differential equation (2), with the help of (1), and substituting the resulting value of K in Y, we rewrite (1) as

$$Y(\mathrm{t}) = \alpha e^{ast} + \beta \tag{3}$$

where $\alpha = aK(0) + (L/asT)(a-i)(asT-1)$
and $\beta = (L/asT)(a-i)$

If we now represent the index of long-run benefits by the total stream of national income over the length of the loan maturity period T, this is given by

$$y = \int_0^T Y(\mathrm{t})d\mathrm{t} \tag{4}$$

Using (3) in (4) and after integration,

$$y = \frac{\alpha(e^{asT} - 1)}{as} + \beta T \tag{5}$$

If we now want to find out the impact of a change in the interest rate charged on the foreign loan on this index of long-run benefits, we take[3]

$$y_i = \frac{\partial y}{\partial i} = \frac{L}{a^2 s^2 T} \cdot \left[(e^{asT} - 1)(1 - asT) - asT\right] < 0 \tag{6}$$

This means that a rise in the interest rate will reduce the long-run benefits from the loan, which is an expected result.

Similarly, if we want to find out the impact of a change in the length of the maturity period, T, on y, we take

$$y_T = \frac{\partial y}{\partial T} = \frac{L(a - i)(e^{asT} - 1 - asT)}{(asT)^2} + Y(T) \tag{7}$$

[3] Suppose $F(x) = (e^x - 1)(1 - x) - x$, then $F(0) = 0$ and $F'(x) < 0$ for $x > 0$; substituting $x = asT$, we can see how equation (6) is negative.

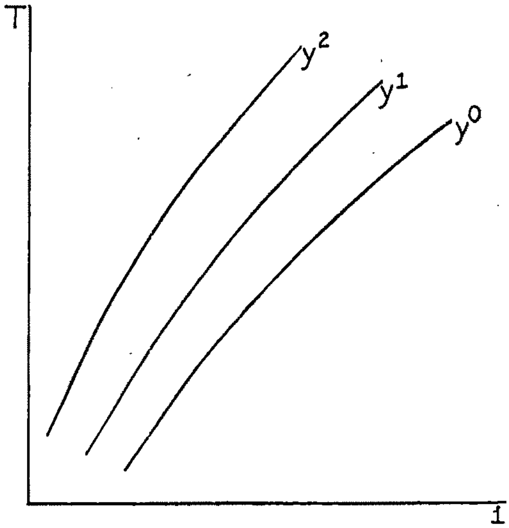

FIGURE 1. INDIFFERENCE CURVES BETWEEN INTEREST RATE AND MATURITY PERIOD

Equation (7) is positive if $a > i$, i.e., if the marginal product of capital is higher than the rate of interest, the longer the maturity period the better. In the opposite case it would be better to repay the loan as quickly as possible, in fact, it does not pay to borrow at all. We shall, therefore, assume $a > i$, and hence (7) is positive.

From (5) we can now work out a relationship between T and i for the same y; since y_i is negative and y_T positive, dT/di is positive. This means that if the total sum of income over the loan period is to be maintained, a higher interest rate on the foreign loan is to be matched by a longer maturity period. Figure 1 shows what may be called the indifference curves between T and i for different values of y. The more to the left a curve on this indifference map is, the higher is the level of the present value of national income associated with it. Thus, with the help of this indifference map one can now plot the coordinates of i and T for alternative loan packages and choose the combination that happens to be on the highest indifference curve.

One can also work out the value of the elasticity of substitution between i and T along such an indifference curve, as given by

$$\epsilon = \frac{dT}{di}\frac{i}{T} = \frac{-y_i i}{y_T T} \tag{8}$$

From (6) and (7) it is not difficult to show[4] that the value of ϵ is less than unity under the sufficient condition that the initial amortization payments do not exceed savings causing decumulation of capital, i.e., $dK(0)/dt \geq 0$, which we assume. This means that the offer of a loan with a maturity period 1 percent shorter than that in another loan must compensate with a *more* than 1 percent lower interest rate compared to the other to be equally attractive for the borrowing country. If there is offer of a loan with 5 percent interest rate and 20 years of maturity, another loan with 30 years of maturity, to be equally attractive from the point of view of long-run benefits of the borrowing country, may charge more than 7.5 percent as interest rate.

Another way of looking at the same result is that the proportionate effect of a rise in the interest rate on the index of long-run benefits is *less* than that of a shortening of the maturity period. This seems to be consistent with the prevailing feeling in international aid negotiations that the recipient countries tend to be more sensitive to changes in the maturity period of loans than to changes in the interest rate.

One objection to the index of long-run benefits we have chosen is that the time horizon exactly coincides with the maturity period. The general case where the long run exceeds the loan period is quite complicated. In one special case, however, all of our qualitative results above remain unchanged. This is the case where we rewrite equation (4) as

$$y = \int_0^T Y(t)dt + K(T) \tag{9}$$

The inclusion of the terminal capital stock in the index of long-run benefits is one way of representing the country's concern for income and consumption in the post-loan period. Since it is easy to check that the value of $K(T)$, which we obtain after integration in equation (2), is decreasing in i and increasing in T, and since $[K_i(T) + K_T(T)]$ is positive under the assumptions we have made so far, it is quite simple to show that, as before, $y_i<0$, $y_T>0$, $\epsilon<1$.

Another point about our index of long-run benefits is that it has been measured in terms of the simple sum of national income over the length of the loan maturity period. Implicitly we have assumed the social discount rate to be zero. What if the social discount rate is positive and the index of long-run benefits is given by the present value of the stream of national income over the loan period discounted at a positive constant rate ρ? Equation (4) is now replaced by

$$y = \int_0^T Y(t)e^{-\rho t}dt \tag{10}$$

and equation (5) by[5]

$$y = \frac{\alpha[e^{(as-\rho)T} - 1]}{as - \rho} + \frac{\beta(1 - e^{-\rho T})}{\rho} \tag{11}$$

If we now want to find out the impact of a change in the interest rate charged on the

[4] From (6) and (7),

$$y_T T + y_i i = Y(T)T + \frac{L}{as^2T}[(e^{asT} - 1 - asT) - isT(e^{asT} - 1)]$$

Putting the value of $Y(T)$ from (3), this is positive if

$$K(0) > L\left(\frac{1}{2 + asT} - \frac{(a-i)}{a}\right)$$

which is satisfied if $dK(0)/dt$ in equation (2) is nonnegative, i.e., if the initial amortization payment does not exceed savings causing decumulation of capital in the initial period. This, we may assume to be valid without much strain on the realism of the model.

[5] Equation (11) is derived under the assumption of $as \neq \rho$. When $as = \rho$,

$$y = \alpha T + \frac{\beta(1 - e^{-\rho T})}{\rho}$$

$$y_i = \frac{L}{\rho^2 T}[(1 - \rho T)\rho T - (1 - e^{-\rho T})] < 0$$

and

$$y_T = \frac{L(a - i)}{\rho^2 T^2}(\rho T - 1 + e^{-\rho T}) + e^{-\rho T}Y(T) > 0 \quad \text{for } a > i$$

foreign loan on the new index of long-run benefits, we take

$$(12)\quad y_i = \frac{Le^{-\rho T}}{asT}\left[\frac{(e^{asT} - e^{\rho T})(1 - asT)}{as - \rho} - \frac{(e^{\rho T} - 1)}{\rho}\right] < 0$$

Thus, the earlier result about the effect of a change in the interest rate goes through. As for the effect of a change in the length of the maturity period,

$$(13)\quad y_T = \frac{e^{-\rho T}L(a - i)}{asT^2}\left[\frac{(e^{asT} - e^{\rho T})}{as - \rho} - \frac{(e^{\rho T} - 1)}{\rho}\right] + e^{-\rho T}Y(T)$$

It is easy to show that (13) is positive under our assumption of $a>i$, again confirming our earlier result. This means that our earlier results about the indifference map in Figure 1 remain intact.

What about the elasticity of substitution, ϵ, between i and T? Here, under the following sufficient conditions[6] our earlier result of $\epsilon<1$ goes through:

(a) $\frac{dK}{dt}(0) \geq 0,$ which we have assumed before,

and

(b) $a \geq i\rho T$

Condition (b) is restrictive, but in most practical cases likely to be satisfied. For example, if the capital-output ratio is 3:1, the interest rate is 8 percent and the social discount rate is 10 percent, even as long a maturity period as 40 years will satisfy this sufficient condition. Under these sufficient conditions (a) and (b), the proportionate effect of a rise in the interest rate on the present value of national income is *less* than that of a shortening of the maturity period. Our earlier case $\rho=0$ is only a special case satisfying condition (b).

[6] From (12) and (13), and after simplification,

$$y_T T + y_i i = \frac{Le^{-\rho T}}{asT}\left[\frac{(e^{asT} - e^{\rho T})(1 - isT)}{as - \rho} - \frac{(e^{\rho T} - 1)}{\rho} + \frac{sT^2}{L}Y(T)\right]$$

It is easy to show that this is positive if: (a) $(dK(0)/dt) \geq 0$ and (b) $a \geq i\rho T$, since from (2) and (3),

$$Y(T) = \frac{dK}{dT}(0)\frac{e^{asT}}{s} + \frac{L}{asT}[a + i(e^{asT} - 1)]$$

Recent Exercises in Growth Accounting: New Understanding or Dead End?

By RICHARD R. NELSON*

The growth accounting literature has been enriched recently by several major quantitative studies and a sophisticated technical dialogue.[1] The obvious high quality of this work may lead some economists to think that great progress has been made in our understanding of economic growth and that we are nearly home. I suggest that while recent research has increased our knowledge, studies of this sort have run into sharply diminishing returns and soon will arrive at a dead end leaving many essential open questions. The basic limitations of growth accounting discussed here are well known to many practitioners. One is the fundamental arbitrariness of the techniques that have been employed to distinguish between movements along a production function and shifts in that function. The second is the possible major misspecification involved in implicitly treating experienced growth as the sum of the contributions made by separate factors. These basic limitations have been repressed in the recent discussions and it seems important to bring them clearly into view again. Because of these limitations, growth accounting has not really illuminated some of the central questions of growth theory and growth policy, which I will discuss in the concluding section.

I. The Problem of Competing Explanations

From its beginnings, growth accounting has been concerned with trying to estimate how much of growth can be explained by movements along a production function, and how much should be attributed to advances in technological and organizational competence. However the early studies recognized quite explicitly the difficulties, perhaps even the theoretical impossibility, of distinguishing between alternative explanations of observed growth patterns without rather strong a priori assumptions.[2] Some of the recent studies appear to give the impression that on the basis of rather weak a priori assumptions there is a theoretically correct way of distinguishing movements along a production function from shifts in it. It seems important, therefore, to review the basic problem.

The difficulty can be seen sharply if one assumes the following stylized aggregative facts.[3] Output (*GNP*) has been growing at the same rate as capital and at a faster rate than labor; hence the capital-output ratio has been constant and output per worker and the capital-labor ratio have been rising. Factor shares have remained constant; thus the rate of return on capital has been constant and the wage rate has risen. These "facts" very roughly characterize the *U.S.* growth experience that the accounting exercises seek to explain. Consider the following two competing explanations, both consistent with the time-series data. One is that the underlying production function is Cobb-Douglas (of unitary elasticity of substitution) and technical change has been neutral in the sense of Hicks. The second is that the underlying production function has an elasticity of substitution less than one, and that technical change has been labor saving. The

* Professor of economics, Yale University. I am indebted to Carlos Diaz Alejandro, Robert Evenson, William Fellner, Yoav Kislev, and William Nordhaus for useful discussion and criticism. None of these necessarily agrees with all or any of the thrust of this paper.

[1] In particular there is the important study of Zvi Griliches and Dale Jorgenson (1967), discussion of this work by Edward Denison, and the attempt at reconciliation by Griliches and Jorgenson (1970). M. Ishaq Nadiri recently has presented a general discussion of the growth accounting literature.

[2] See for example the cautious remarks of John Kendrick

[3] Robert Solow (1970) makes use of these same stylized facts.

first interpretation is depicted in Figure 1, the second in Figure 2. Points (*a*) and (*b*) in the two figures are identical and the slopes of the curves (the marginal productivity of capital) at those points also are identical. Thus both interpretations are consistent with the input, output, and factor price data.

The two interpretations are different in the following "growth accounting" sense. In the case of Figure 1, output per worker would have grown by Δ_{11} if capital per worker had grown as it did, but the production function had not shifted. Δ_{12} represents the increase in output per worker not explained by growth of the capital-labor ratio and hence due, in some sense, to technical change. In Figure 2, Δ_{21} can be attributed to growth of capital per worker and Δ_{22} to technological change in the sense above. In the latter interpretation, the lower elasticity of substitution means that less of productivity growth can be attributed to growing capital intensity, hence more must be attributed to improved technology. As Peter Diamond, Daniel McFadden, and Miguel Rodriguez (among others) have pointed out, since both interpretations are equally consistent with the time-series data there is no way to choose among them, without a priori assumptions.

In fact, the growth accounting exercises have not proceeded by attempting to specify a particular "production function" and estimate its parameters. Rather the strategy is somehow to build up an input "index" that

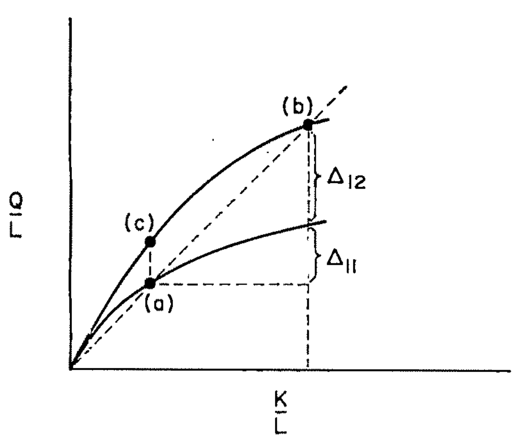

FIGURE 1

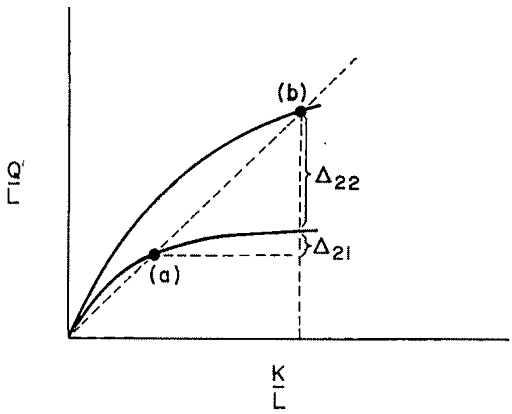

FIGURE 2

ALTERNATIVE INTERPRETATIONS OF PRODUCTIVITY GROWTH

measures the contribution of growth of input quantity (disaggregated so that "quality" changes can be accounted) to output growth without explicit commitment to a particular production function. There is a semantic problem here. The "*input* index" really is an estimate of *output* under the assumption of constant technology. In any case, this research methodology does not avoid the problem but simply evades it.

The use of a particular weighting or index scheme for input growth is the growth accountant's de facto assumption about the shape of the production function. A starting place for all growth accounting is the assumption that, if the neoclassical theory holds, at any time factor prices equal marginal productivities. Thus it is natural to weight factor inputs by their prices. But prices when? They are likely to vary over the period in question. There seems to be a belief that use of the Divisia index is the correct answer.[4] The Divisia index weights inputs at any moment of time by their prices at that moment. Ideally in using the Divisia method one would estimate the instantaneous growth of output due to factor increase by the method proposed by Solow (1957). Let

[4] Griliches and Jorgenson seem to claim this. The original statement of the correctness of the Divisia formula seems to be Marcel Richter's.

dQ^*/Q be instantaneous output growth due to input growth.

$$(1) \quad \frac{dQ^*}{Q^*} = S_L \frac{dL}{L} + S_K \frac{dK}{K}, \text{ where of course,}$$

$$\frac{dQ}{Q} = \frac{dQ^*}{Q^*} + \frac{dA}{A}$$

Integration of the right-hand side of equation (1) over the total time period would appear to give total output increase due to input growth (Δ_{11} of Figures 1 and 2).

$$(2) \quad \log Q^*(\mathrm{T}) - \log Q^*(0) =$$

$$\int_0^{\mathrm{T}} \left(S_L(\mathrm{t}) \frac{d \log L(\mathrm{t})}{dt} + S_K(\mathrm{t}) \frac{d \log k(\mathrm{t})}{dt} \right) dt$$

I shall argue that appearances are deceiving.

In practice factor price weights (shares) cannot be reestimated continuously but on a yearly (or other periodic) basis. If periods are short enough there is no real problem introduced here. The real problem is that we are not concerned with growth over a "year" but rather over a rather lengthy period, say the half century since the end of World War I. When considering a period of this length the fact that the overall period is divided up into short periods does not help; a large number of subperiods need to be added up over the total period. The problem does not go away. It is the finiteness of the total comparison period that causes the difficulty.

The time path of factor prices or shares over finite time is what it is because of both changes in factor ratios and technological change. The Divisia formula fails to distinguish between alternative explanations of factor prices. Thus under the interpretation of Figure 2 the capital share would have fallen but for the fact that technical change was capital using. If one wants to attribute to factor growth only what output growth would have been had technology been constant, then one must use in equation (2) not actual "shares," but the time path of shares as they would have been had technology not changed.[5] But to do this requires that one be able to specify the original production function which was the original impasse.

The route out of the impasse requires more specification based on other data. For example, one could attempt to estimate the elasticity of substitution from engineering design data. Or, if one had access to cross-section data on outputs and inputs as well as time-series data, under certain assumptions one might be able to sort out the shape of the production function from shifts in that function. Assumptions about momentum or independence can facilitate discrimination. For example, one could assume that the rate of technical change were constant. Then if that assumption were correct, and there were considerable variation over time in the rate of growth of the capital-labor ratio, one might be able to sort out among competing hypotheses. Fellner takes such an approach. In any case, in order to do growth accounting in a nonarbitrary way, we need knowledge that goes beyond the data that are used in the growth accounting.

II. The Meaning of Growth Attribution

Let us assume that the problem described above is solved. Then it would be possible to pose the following question: how much growth would we have experienced had only technology changed, or only capital, or only labor, or only capital and labor, or various other combinations of factors. However, it is uncertain what meaning one would give to the answers. If by attribution to a particular factor we mean the growth that would have occurred had it alone changed, the relative attribution to growth of different factors is not independent of the time period in ques-

[5] That is the shares need to be written explicitly as a function

$$S_i\left(\frac{K}{L}(\mathrm{t}), A(\mathrm{t})\right)$$

Equation (2) needs to be specified with

$$S_i\left(\frac{K}{L}(\mathrm{t}), A(0)\right)$$

The Richter specification of equation (2) does not do this.

tion, even if all factors are changing at a constant rate. Further, while using this meaning of attribution the sum of the attributions adds up to total growth for very small time periods, they may not add up to total growth if finite time periods are considered. These points were raised earlier by Herbert Levine and Benton Massell but seem to have been ignored in the recent discussion.

Assume that interpretation 1 is known to be correct, that the production function is Cobb-Douglas and technical advance is neutral, and that all factors were growing at constant rates. Assume that by attribution to a factor we mean the amount of output growth that would have occurred had that factor alone changed. Measure the instantaneous growth rates associated with the yearly growth rates of capital and labor. Label these λ_K and λ_L. Estimate the instantaneous rate of technical progress by the Solow method using the instantaneous rate of output growth. Call this λ_A. In the case of infinitesimally small changes the attribution of any factor of growth relative to another, or relative to total growth, is easily computed from these constants. All is nice and neat, with attributions to individual factors adding up to total growth.

All the neatness goes when finite time periods (say between 0 and T) are considered. For capital and technological change the attribution ratio is as follows:

$$(3)\quad \frac{\text{Attribution to Technical Advance}}{\text{Attribution to Capital Growth}} = \frac{e^{\lambda_A T} - 1}{e^{\lambda_K s_K T} - 1}$$

Relative attributions to different factors are sensitive to the time period in question. In the Cobb-Douglas case the percentage of total growth explained by growth of any particular factor, with the others held constant, shrinks to zero as the time period increases. For technical advance, for example:

$$(4)\quad \frac{\text{Attribution to Technical Advance}}{\text{Total Growth}} = \frac{e^{\lambda_A T} - 1}{e^{(\lambda_K s_K + \lambda_L s_L + \lambda_A)T} - 1}$$

This expression clearly goes to zero as T increases.

At first glance all this seems strange, but it is not. The problem is the same one that plagued the profession many years ago when it was trying to attribute total product (rather than growth) between the different factors. We learned then that this was impossible. We could attribute at the margin. But there was no way of attributing shares of the total.

To see the problem from another perspective look again at Figure 1. Δ_{11} measures how much output would have grown had technology remained constant. It is analogous to the numerator of equation (3). Δ_{12} is the measure of the contribution of technological change measured as a residual, but it does not measure how much output would have grown had capital remained constant. It is not analogous to the denominator in equation (3). The distance between points (*c*) and (*a*) measures that. Call this Δ_{12*}. This is the same as Δ_{12} only for very small changes. For finite changes, Δ_{11} plus Δ_{12*} do not add up to total growth. To get total growth one must add an "interaction term."

Experienced growth is unlikely to be the simple sum of the contributions of separate factors. One could take the position that the degree of interaction among the factors is small, and that the separable contributions of the different factors are like the first terms of a Taylor's expansion. This is an arguable position but rests on an assumption about the nature of the production function and about technical change. The approximation might be good, and it might be poor. If the time period in question is considerable, Taylor series arguments are questionable.

The recent literature appears to get around these problems by posing the question in terms of the contribution of average yearly growth of capital, or labor, or technical advance, to average yearly growth of output. However, the contribution of technical change to growth, or of expansion of any particular factor, during any year is not independent of what happened to the other factors prior to that year. Consider a year toward the end of the accounting period. The

contribution of, say, capital during that year is as large as it is because labor and technology had advanced during the prior periods as much as they did. The "average period" metaphor thus may be extremely misleading. And it will be if "interaction" is important.

In principle the questions are answerable. But the answers will require investigations that go beyond growth accounting exercises.

III. What is the Purpose of Growth Accounting?

I take it that the principal purpose of growth accounting has been, and still is, the estimation of various magnitudes which our growth theory suggests are important, testing various propositions or alternative specifications of that theory, and illuminating better the phenomena that a growth theory must explain. Growth accounting is a complement to more traditional (regression) techniques of estimating and testing growth theory. In fact growth accounting has greatly and fruitfully influenced the evolution of our understanding of economic growth. But some of the recent studies seem to imply that somehow the growth accounts really explain growth. I do not see how they can. A growth accounting is not a tested theory of growth.

What do I mean by a tested theory? If we had one, what would it do for us? In the first place we would expect the theory to give an explanation, an account (if not an accounting) of past growth. This immediately poses the question—an account of what phenomena? What needs to be explained? Certainly the aggregative time-series data (at an economy or sector level) on output, input, and prices. Nations and industries have grown at varying rates over time. Different countries and industries have grown at different rates. An explanation is called for.

What do we mean by an explanation? Obviously an explanation implies ability of the theory to replicate reasonably closely the phenomena to be explained, given estimable parameter values. However this is not all we require of a theory. There generally are many alternative explanations that fit past finite data reasonably well. Economists want a theory which will predict as well as explain. And we set premium on the ability of a theory to guide policy. Thus I assume that an acceptable "explanation" does not leave unanswered questions like the two probed in the preceding sections because they imply different things about the future. Prescription as well as prediction hinges on which of these specifications is correct.

In economics, as in all sciences, acceptable explanations must take on certain kinds of analytic forms. Most of growth accounting is motivated by an underlying neoclasical theory of economic growth. Solow (1970) has recently provided a survey of the grab bag of models generally included under this label. Without prejudice regarding the basic question of whether this is the most useful kind of a growth theory, it is important to note that neoclassical theory itself does not answer the above questions. Within the spirit of the theory, there are alternative specifications that answer the questions above in different ways. The questions thus are empirical ones, within the theory.

However, the spirit of growth accounting loads the die. Growth accounting makes "most sense" in a model that assumes that considerable sustained output growth is possible from factor growth, and that factor complementarity is not particularly important. The implicit theory is that output is a function of technology, effective capital, and effective labor. The elasticities of substitution among capital of different qualities, and among labor of different qualities, are assumed to be infinite or at least very high.[6] The elasticity of substitution between effective capital and effective labor implicitly is assumed to be relatively high, and certainly not close to zero. There is considerable ambiguity regarding the connection between technical advance and capital and labor quality. Basically, however, growth accounting as practiced makes sense only if it is assumed that the generation and incorporation of new technology requires only modest amounts of new capital and is not particu-

[6] This is so for models that aggregate capital and which "quality adjust" labor. Not all of the neoclassical models are of this kind.

larly associated with labor of a particular kind or quality.[7]

Under these specifications growth of output per worker can continue so long as the capital-labor ratio grows. While for sustained growth the critical value of the elasticity of substitution is unity, for periods of as long as a quarter century little deceleration of growth of output per worker would be experienced at the rates of factor growth we have experienced, even for an elasticity of substitution as low as one half. Similarly the growth accounting interaction term would not be particularly important over such a time period. Postwar growth of output could be explained quite well as the sum of the separate contributions of improved technology, and increases in effective capital and labor.

However, consider the following alternative model which is at almost an opposite extreme regarding the two questions. Solow, Tobin, von Weizsacker, and Yaari have proposed a model in which any productive increase in the capital intensity of production requires new technology. If technological advance stopped today, output per worker would grow for a while as firms that had been working with older capital shifted over to new and more productive machines. But once they had done this, growth of output per worker would cease. In this model new technology is needed in order to permit productive increase in capital intensity but new technology cannot get into practice without new capital. Let me add to this structure the following. The production and installation of new technology requires educated workers; further, in the absence of technological advance educated workers would be doing nothing different than uneducated workers and would not be more productive.

In this model it is natural to think of technological advance as the binding constraint on the system; certainly sustained growth would be impossible without technical advance. Traditional growth accounting would be nonsense, because of the strong complementarity among technological change, capital growth, and education. To estimate the contribution of technical change by subtracting an estimated contribution of increases in capital and education clearly would be absurd.

The differences between the models involve not only interpretation of past experience, but prescription of how to improve future performance. In the first model it is natural to think of a number of different, and roughly separable, factors that might increase the growth rate. Choice among say more research and development, education, and more physical investment can be made on the basis of rate of return, or cost benefit calculations. While in the long run the complementarity among the factors means that the rate of return on one is not independent of the level of the others, for shorter run calculations this can be ignored. The second model forces policy thinking in terms of complementary packages. Thus a policy in support of *R&D* is thought of as needing support by a policy of training scientists, and as being made effective through policies to facilitate physical investment. An interesting example of a policy which, to be successful, required a rather complex package is the so-called green revolution, as described by Yujiro Hayami and Vernon Ruttan.

To repeat the argument of the earlier sections, we cannot confidently distinguish between these two opposite extremes on the basis of growth accounting exercises and time-series data alone. If we limit ourself to neoclassical formulations, the right model probably is somewhere in between the two cases discussed above, but for many sectors may be closer to the second model than the first. We economists tend to be far too facile with our chalk (or equations) in drawing isoquants into regions of factor proportions that never have been experienced. I would bet that in the absence of considerable research and development reconnaissance of the terrain, firms venturing into technologies with significantly higher capital-labor ratios than actually have been experienced will tend initially to make mistakes, and will experience a considerable amount of learning

[7] For a similar discussion, see Fellner.

costs before achieving significant gains in output per worker. Either research and development (learning before doing) or learning by doing (certainly also a form of *R&D*) is required to make the isoquant more elastic beyond the experienced range. Similarly I believe that economists have been much too mechanical in their treatment of the returns to education. It seems a safe bet that a large share of the returns to higher education are tied up with the processes of technical advance and the chain of economic adjustments thereby set in train.[8]

These are conjectures. We must learn if they are correct, and it is possible to test them. However it strikes me that "growth accounting" is a low marginal returns strategy.

[8] Fellner and Moses Abramowitz and Paul David make similar points. And Hayami and Ruttan make them in their concept of "meta" production function, and their stress on the role of education in innovation and diffusion. Finis Welch discusses these points regarding education, and provides some interesting evidence that education pays off when technology is changing.

Faculty Salaries, Promotions, and Productivity at a Large University

By DAVID A. KATZ*

Recently, there has been considerable concern regarding the problems associated with evaluating and rewarding university professors. While these problems have always existed, they have been compounded by the recent economic recession and the growth of political activism which transcends the traditional line between student and teacher.

A recent AAUP report in June 1971 for example cited the "... notable increase in faculty salary grievances, particularly in the form of assertions that a particular salary has been determined upon either for reason violative of academic freedom or on the basis of improper or inadequate evaluation" (p. 187). The report went on to recommend the development of clearly specified and understood criteria for evaluating professors which would hopefully reduce the number of grievances.

Unfortunately, little is known about the process of evaluating and rewarding university professors. One possible reason may be the difficulty of obtaining good data on professors. Secondly, the analysis of such data requires a thorough knowledge of the institutional processes of wage determination. Frequently, it is difficult or impossible to obtain this data and knowledge.

Fortunately, it was possible to obtain the necessary data from a large highly ranked public university for an intensive study of the determinants of faculty salaries and promotions. While it would have been desirable to conduct a multi-university study, this was not possible given the limited time and funds. However, because of the techniques employed in this study, it is expected that the methods can be applied at other large colleges and universities.

I. Methodology

This section presents the methodology which was used to analyze the factors important in salary and promotion decision making at the university level. The primary purpose was to develop a more rational means of evaluating and rewarding university professors.

Personal interviews with the chairmen or heads of nine of the eleven departments in this study (one chairman refused to be interviewed and the other was never available) were conducted to gain a better understanding of the salary and promotion processes. Once budget allocations are made to individual departments, the department chairman sometimes in consultation with his faculty executive committee determines the salaries to be received by individual faculty members. Although final decisions regarding salaries are almost always made at department levels after receiving their budget allocations, department promotional decisions are subject to much greater scrutiny by higher administrative echelons, especially the college and all-university committees on promotions.

Only two of the departments had written policy statements regarding salaries and promotions, available to faculty members

* Assistant professor, department of economics, University of Missouri at Rolla. The research was part of a Ph.D. dissertation in economics, University of Illinois, 1971. I would like to thank the following people: My wife, Debbi, for her considerable help with the tedious task of collecting and coding the massive amount of data; my dissertation advisor, Paul T. Hartman of the University of Illinois, M. Eugene Moyer of the department of Health, Education, and Welfare who helped me considerably in the early stages of the study; John Terwilliger and his assistant Walt Tousey, of the University of Illinois office of administrative studies; David DeVries, now of the Johns Hopkins Center for Study of Social Organization of Schools for allowing me to use the journal ratings constructed by him and Fred E. Fiedler; David Brown, Miami University Provost, for providing the undergraduate school rankings; also, an anonymous referee for his valuable suggestions.

upon request. It will probably surprise no one that the salary and promotion processes within departments are usually cloaked in secrecy.

Very friendly and willing to help, the chairmen and heads explained what criteria they used to judge individuals, but seldom could they provide the relative weights assigned to these criteria. Frequently, they either began or ended by quoting the faculty handbook, supposedly a good source of knowledge regarding salary and promotion policies. "Teaching, research, and public service to the university" were the repeated replies of the chairmen and heads.

After pressing the department administrators on their techniques of evaluating teaching, they usually admitted they knew little about the teaching abilities of professors in their departments, although they thought they knew who were the "good" and "bad" teachers. Without any basis upon which to judge teaching performance, other factors more easily measurable must account for raises in rank and pay. An alternative hypothesis later to be rejected is that salary and promotion decisions were completely arbitrary, with personality and politics playing the major roles.

It became clear that research ability, publication record, and national reputation were the most important factors influencing salary and promotion decisions. The department chairmen and heads agreed they could easily evaluate research ability by examining the quality of journals (usually refereed) in which articles appeared and by reading book reviews. Since department chairmen are seldom experts in every field within their disciplines, this approach is probably better than attempting to judge the merits of research and publication themselves. Especially in large departments, the task of reading and judging everything published would be impossible. Therefore, the quality of an article or book can more easily be ascertained by noting whether or not the article was rated good by experts (as in the usually high quality refereed journals) or if the book received good reviews.

Public service (for example, a public lecture or the editing of a journal), administrative and committee work were the other factors to which department administrators said they gave weight. A current file is kept on all professors containing detailed information on publications, teaching and public service activities, administrative assignments and committee work. It is regularly consulted by department administrators when making salary and promotion decisions.

In the next phase of the study, data from university records were collected which would measure the most important salary and promotion factors. These records contain information on department, years between promotions, date of first appointment, date of birth, degrees and years received, where degrees were received, publications, dissertations supervised, student evaluations of teaching ability, and hours spent per week on committees, public service, administration, teaching, and research. Also, sex, administrative title if any, appointment type (9- or 11-month), percent appointment time, and current salary are included.

As publication records were recorded for each professor, an article which appeared in one of the top journals in any particular discipline was also noted. Recently, David L. DeVries and Fred E. Fiedler developed fairly reliable indices of journal quality in several disciplines. Indices existed for nine of eleven departments in this study and the other two were obtained using methods similar to the DeVries and Fiedler study.

All professors at assistant professor and above in eleven departments were selected for study (596 in total—1969–70 academic year). These departments represent a good cross-section of the major disciplines taught at almost all large colleges and universities—economics, electrical engineering, English, French, history, mathematics, physics, political science, psychology, sociology, and zoology.

II. The Salary Model

The dependent variable is

S = 1969–70 academic year salary corrected to a 100 percent departmental basis.

The independent variables are listed below along with some theoretical justification for inclusion when necessary:

B = number of books published either authored or edited, lifetime.

A = number of articles published, lifetime.

E = number of articles published in the very best journals in a particular discipline ("excellent" articles).

T = a dummy indicating whether or not a professor is ranked in the top 50 percent of all instructors by vote of students.

F = number of dissertations supervised since 1964, a measure of research and graduate teaching ability. Lifetime dissertations were not available.

P = number of hours devoted per week to public service activities in 1970.

C = number of hours devoted per week to committee assignments in 1970.

Y = number of years since highest degree, a measure of experience.

D_1 = a dummy indicating whether or not a professor is a social scientist (economics, political science, or sociology).

D_2 = a dummy indicating whether or not a professor is a physical or laboratory scientist (electrical engineering, mathematics, physics, psychology, or zoology).

D_3 = a dummy indicating whether or not a professor is in the humanities (French or history).

D_4 = a dummy indicating whether or not a professor is in the English department. D_1 to D_4 were included to measure possible differences in market supply and demand for the various major disciplines. D_3 and D_4 were not combined because of considerable salary differences found in previous regression runs.

U_1 = a dummy indicating whether or not a professor received his undergraduate degree from schools containing the top 10 percent of all faculty in the country.

U_2 = a dummy indicating whether or not a professor received his undergraduate degree from schools containing the next 70 percent of all faculty.

U_3 = a dummy indicating whether or not a professor received his undergraduate degree from schools containing the bottom 20 percent of all faculty.

U_4 = a dummy indicating whether or not a professor received his undergraduate degree from a foreign school or one that was not ranked.

G = a dummy indicating whether or not a professor received his highest graduate degree from the bottom groups of graduate school departments. U_1 through G were included to measure quality of education.

M = a dummy indicating whether or not a professor had an administrative assignment.

X = a dummy indicating whether or not a professor was a female. This was included to measure the extent of discrimination, if any.

N = a dummy indicating whether or not a professor was on an 11-month appointment.

R = a dummy indicating whether or not a professor possessed the Ph.D.

The results of this regression are reported in Table 1. Most variables are significant at the 1 percent level and almost all the remaining ones at the 5 percent level. While this regression was capable of explaining 68 percent of the total variation in current salary, the standard error was rather large—$2946.

The following major conclusions can be made regarding salary determination. 1) Teaching ability as measured by student evaluations is inconsequential in the reward system, while publications are paramount. 2) Teaching and research ability at the Ph.D. level, as measured by dissertations supervised, is a most important determinant of salaries. 3) Although public service and committee work are rewarded, the returns are not spectacular. 4) The returns to a graduate education are significantly higher if the degree is received from one of the top graduate school departments. 5) Similarly, it pays not to graduate from one of the bottom ranked undergraduate schools. 6) Social science professors are paid significantly more than those in the humanities, and slightly

more than those in the physical and laboratory sciences. 7) Finally, the empirical results tended to strongly support the hypothesis of sex discrimination—women were paid $2410 less in 1969 than men. Each of these conclusions will be discussed more fully below.

Of all variables included in this regression, student evaluations of teachers were the least predictive of salary. While the department chairmen and heads interviewed indicated they rewarded teaching ability, student evaluations were probably not a source of knowledge regarding teaching performance. This conclusion is supported by the fact that most of the department chairmen interviewed had great mistrust of student ratings

In contrast, the publication of a book, article, or excellent article during a professor's lifetime was worth an extra $230, $18, and $102, respectively, in 1969. In a previous regression run, reviews were found to be totally worthless. There were not enough observations on other types of publications to test their significance. The publication regression coefficients represent the salary differentials in 1969 as a result of past publication. Consequently, the actual value of an article or book is measured by discounted

lifetime value which is a function of age.

Another related problem in the interpretation of the regression coefficients is the possibility of nonlinearity. For example, two books or articles may not be equal to twice the value of one. Because of this problem, the linear regression was found to poorly estimate two of the three publication variables—books and articles, but not excellent articles. Nonlinearity was not found to be a serious problem in estimates of the other variable coefficients.

Table 2 presents the average remuneration for various levels of publishing after holding constant all other variables. Diminishing marginal returns to publishing are quite evident in this table. For example, a professor who published one book received $451 more in 1969 than those who had not published any books. However, a professor who published more than two books received an additional $370 per book. Similarly, a professor who published nine to twenty articles received an additional $89 per article in comparison to the under-nine article group which received an additional $111 per article.

TABLE 2—AVERAGE RETURNS TO PUBLISHERS

1–2 Books	$451/book
>2 Books	$370/book
<9 Articles	$111/article
9–20 Articles	$ 89/article
21–38 Articles	$ 74/article
>38 Articles	$ 57/article

In addition to publication record, number of dissertations supervised (since 1964 only) was included as a measure of graduate teaching and research ability and national reputation. Since a dissertation is original research, the supervising of a dissertation requires the same ability which research and publication requires. As proof of this, number of dissertations supervised was highly predictive of current salary (coefficient = $489).

Each additional hour per week of public service or committee work was worth an additional $89 and $156, respectively, in 1969. Assuming a 32-week academic year, this represents a payment of only $2.78/hour for public service and $4.88/hour for committee work.

The graduate school rankings were based on a survey by Allan Cartter of department chairmen and senior and junior professors nominated by deans of 106 graduate schools. The quality of graduate faculties and the effectiveness of doctoral programs were rated by these chairmen and professors. This study used the rated effectiveness of the doctoral program which is grouped into four classes: 1) extremely attractive; 2) attractive; 3) acceptable plus; and 4) not attractive. Because no significant salary differences were found among groups 2–4, they were combined and compared to the top group, extremely attractive. A salary differential of $875 was found to exist in favor of the top group.

The undergraduate school rankings were based on a study by David Brown (1965) which rated 1,121 4-year American colleges and universities. Table 3 presents the groupings of these 1,121 schools. For example, the top 28 schools have 10 percent of the total fulltime faculty but represent only 3.2 percent of the total 1,121 schools, while the bottom 428 schools have only 20 percent of the total faculty but represent 38.2 percent of the 1,121 colleges or universities. Size and quality are therefore strongly correlated in Brown's study.

TABLE 3—UNDERGRADUATE SCHOOL GROUPINGS

Group	Number of Schools in Group	Percent of All Faculty in Group	Percent of All Schools in Group
1	28	10 (top 10)	2.4
2	47	10 (next 10)	4.2
3	134	20 (20–40)	12.1
4	201	20 (40–60)	17.9
5	283	20 (60–80)	25.2
6	428	20 (80–100)	38.2

The 596 professors in this study received their undergraduate educations mostly from the top groups of schools: Group 1, 21 percent; Group 2, 12 percent; Group 3, 23 percent; Group 4, 13 percent; Group 5, 8 percent; Group 6, 4 percent; foreign and other,

16 percent, and missing, 3 percent. The only undergraduate variable which was significant in explaining current salary was Group 6. Apparently, an education at the bottom 428 schools in the country was worth $2025 less than Group 1.

In the early 1960's, a time of excess demand for all disciplines, Brown (1967) ranked 23 disciplines in order of their relative market demands. On a scale of most to least in demand the departments in this study were ranked as follows: electrical engineering (1), mathematics (4), physics (5), economics (6), psychology (10), sociology (11), political science (14), zoology (20), English (21), history (22), and French (23).

Department was therefore included to account for possible differences in market supply and demand for the various disciplines. Social science professors were the best paid after holding constant all other important variables. They earned $791, $1181, and $2293 more than physical-laboratory scientists, humanities (French and history), and English professors, respectively. In the Brown study cited above, English, French, and history were the disciplines least in demand.

The mean 1969 salary for male professors in this study was $16,078, while only $11,233 for women (there were 49 women in the study). After holding constant all other variables, women made $2410 less than men. Therefore, $2410 is a measure of the extent of sex discrimination and $2435 ($16,078 − $11,233 − $2410) is a measure of the salary differential due to other factors, for example, productivity and experience.

An index was constructed to compare the publication records of men and women. This same index was used to compare the publication records of the three ranks (see Table 4). In forming the index the significant publication coefficients (books, articles, and excellent articles) were multiplied by the number of books, articles and excellent articles for each professor. For example, a professor with one book, ten articles and two excellent articles has a "Productivity Index" value of $614=(230\text{x}1)+(18\text{x}10)+(102\text{x}2)$.

The mean Productivity Index value for men was 846 while only 261 for women (difference significant at 1 percent level). This was the clearest indication of the lower productivity of women. Although the following differences were not significant, the mean experience for men in the sample was 13.3 years versus 11.7 years for women; 94 percent of the men had Ph.D.'s versus 88 percent of the women. Men and women had about the same teaching effectiveness ratings.

No significant difference appeared to exist between men and women regarding quality of undergraduate school. In contrast, a significantly higher percentage of women earned their highest degrees from the lower quality graduate school departments: Top Group (39 percent of the men, 22 percent of the women); Second Group (25 percent of the men, 33 percent of the women); Third group (17 percent of the men, 16 percent of the women); Fourth Group (14 percent of the men, 25 percent of the women), and missing (5 percent of the men, 4 percent of the women).

While women devoted fewer hours to public service and administration, these differences were not significant: public service hours per week (men—1.80 hours, women—1.20 hours), administrative hours per week (men—3.83 hours, women—3.46 hours). However, women spent significantly fewer hours on committees (men—3.02 hours, women—1.46 hours).

III. Faculty Promotions and Productivity

To test the extent to which clear standards were applied to promotion decisions, those professors who had received promotions from assistant to associate (249 out of 596 professors) and associate to full professor (183 out of 595 professors) were selected for study. Publication data up to the times of promotions and the total number of years between promotions were available for both groups. Unfortunately, public service and committee data and teaching ratings were recent, and therefore did not accurately measure the extent of involvement in service or committee activities or teaching quality at the times of promotion. If one assumes these do not

TABLE 4—PRODUCTIVITY INDEX BREAKDOWN BY RANK[a]

	0.0	1–100	101–300	301–600	601–1000	1001+
Assistant Professors	22.4	27.1	30.3	15.1	3.0	2.0
Associate Professors	6.4	20.5	27.4	22.0	17.2	6.4
Full Professors	1.6	8.2	15.3	17.5	24.6	32.8

[a] Shown in percent.

change considerably over time as was done with respect to the salary study, then recent values for service, committees, and teaching can serve as proxies for past performance.

In Table 4 the Productivity Index values of professors at the times of promotion to associate and full professors are presented and compared to the records of assistant professors. The index was constructed by multiplying the number of books, articles and excellent articles at the times of promotion (except, of course for assistant professors) by their coefficients in Table 1. The modal value was 101–300 for associate professors; the highest percentage of professors (27.4 percent) was promoted to associate professor after attaining an index value of 101–300. The mean index value was 427 for associate professors and 840 for full professors at the times of promotion in comparison to only 227 for assistant professors (differences significant at 1 percent level).

The fact that the mean Productivity Index values were significantly different among the three ranks supports the conclusion that certain minimal standards for promotion have been practiced. While minimal standards seem to exist, the attainment of this minimum publication record did not guarantee promotion as was indicated by the large number of assistant professors with index values in the 101–300 range (30.3 percent). The mean experience for these assistant professors was only 5 years which suggested that many of them did receive promotions in 1970 given the 6-year tenure rule. (Promotion data is for 1969 in this study.) Therefore, except in unusual circumstances such as extremely high productivity, professors have to wait a certain minimum time before being promoted. This conclusion was supported by the fact that only 21 percent of assistant professors were promoted to associate professors in less than 3 years. The modal value was 3 years, the median 4.8 years, and the mean 5.8 years. Similarly for promotion to full professor, only 17 percent of the associate professors were promoted in less than 3 years; the modal value was 4 years, the median 4.1 years and the mean 4.7 years.

Table 5 compares the rate of productivity publications of associate and full professors before and after promotion. Professors receiving promotions within the last 3 years were excluded because of the possible lag between research and publication. Rate of productivity was calculated by dividing a professor's productivity index by years required to achieve this record.

TABLE 5—RATE OF PRODUCTIVITY COMPARISONS

Rate before promotion to associate professor	=98
Rate after promotion to associate professor	=75
Total Cases=184	
Difference significant at 5 percent level	
Rate before promotion to full professor	=79
Rate after promotion to full professor	=99
Total Cases=138	
Difference significant at 1 percent level	

Productivity declined by about one article per year after promotion to associate professor (difference significant at 5 percent level). However, productivity increased by about the same amount after promotion to full professor (difference significant at 1 percent level). In general, a professor takes a short breather once tenure is granted, but then starts working at his original pace upon attaining the highest rank. Therefore, tenure does not appear to greatly affect lifelong

productivity as measured by publication record.

Teaching ratings did not differ significantly among the ranks. Mean teaching ratings for the three ranks were assistant professor: 5.37; associate professor: 5.42; and full professor: 5.41.

In contrast, public service and committee hours differed significantly among the three ranks. The mean hours per week devoted to public service and committees, respectively, were assistant professor (.92, 1.99), associate professor (1.50, 2.88), and full professor (2.45, 3.51). Therefore, either public service and committees are important variables in explaining rank or some of the perquisites of rank for example are opportunities to lecture to the public, edit a journal, or serve on committees.

The number of hours devoted per week (self-reported) to preparation for teaching did not have any significant effect on a professor's teaching rating. Similarly, the number of hours devoted per week to research had no significant effect on publication record. Professors reported they spent from 0–42 hours in preparation for teaching and 0–70 hours in research. The mean number of hours reported in preparation for teaching was 15 hours, and 19 hours for research.

One of the surprising results of this study was the significant decline in teaching ratings (these are published and distributed to all interested persons) from 1969–70 for those professors with ratings for both years (167 professors). The mean rating for this group was 6.2 in 1969, while only 4.9 in 1970. This may have been a result of changes in the percentile norms from 1969–70. Alternatively, professors may react adversely to published criticism by students.

IV. Recommendations

In general, university administrators make decisions regarding salaries and promotions in an intuitive manner with seldom any clear understanding of the weights they are attaching to various criteria. Consequently, faculty members may have only vague ideas as to how their salaries and promotions are determined. A symptom of the chaotic process is the almost total lack of written departmental policy statements on salaries and promotions. The high standard error of the salary model is further proof of the capriciousness of the reward system.

At present the distribution of rewards among professors in the various departments is arbitrary with no one factor necessarily receiving the most weight. One department may give extraordinary rewards for experience, for example, while another for number of articles published or committee work. Such an uneven distribution of rewards appears to be inequitable. One possible solution might be for the university to establish unambiguous guidelines for departments and colleges which would hopefully result in less arbitrary decisions and fewer grievances.

This study has demonstrated the feasibility of quantifying many of the important determinants of faculty salaries and promotions. If university administrators should decide to institute policy guidelines for departments and colleges to follow, it could serve as a pattern for decision making.

However, some problems still remain before university administrators could adopt this study for use in improving the salary and promotion processes. The foremost of these is the need to define the role of teaching in the reward system. Many administrators and professors feel that the teaching of undergraduates is a minor function at a large university which by its very nature is research and prestige oriented. This view is opposed by a considerable portion of students, administrators, and professors who see the primary role of the university in terms of quality teaching. Since the university in this study is state supported, the final decision in this dispute may rest with the legislative and executive branches, unless university administrators are able to resolve the problem.

If university administrators should decide to institute a teaching rating system of professors, they should be aware of the major problems, especially the great mistrust of student evaluations expressed by so many of the department chairmen and heads. To increase the credibility of teacher evaluations, one possibility might be to poll the

opinions of senior and graduate students only, since presumably they have better knowledge of their particular disciplines than underclassmen. While some have suggested that administrators and colleagues of professors visit classes and seminars to rate faculty members, the results may be worse than senior and graduate student input because the level of tension in having administrators and colleagues visit classes may adversely affect teaching performance.

Administrators should give serious thought to resolving the problems associated with rewarding teaching performance. Otherwise, the state might set standards which would be inconsistent with the goals and purposes of a large college or university, however the latter might be perceived.

Another major area of concern is the salary and rank differential of women versus men. Probably the most important factor accounting for this is the policy of hiring a professor's wife to convince him to accept a job at the university. Supporting this assertion is the fact that about one-half of the women in this study have husbands who are professors at the university and of these about two-thirds have lower rank than their husbands. Consequently, a woman may frequently be considered by administrators as if she were employed on a different basis than her husband, thus reducing her rank and salary.

This study has demonstrated that even after taking into consideration their lower productivity, women are still paid less than men. Although noting the preferential treatment given to hiring women whose husbands are hired at the university, this discriminatory policy in rank and pay is not necessarily justifiable. This complex problem must be resolved by university administrators, or again, as with the case of rewarding teaching effectiveness, the state might step in to solve the problem, but this time in the form of federal action—for example, the cut-off of research grants so important to the functioning of the university.

If the problems of rewarding teaching performance and eliminating sex discrimination are overcome, this study could prove valuable to university administrators. Instead of the present arbitrary and chaotic process of rewarding professors, a more equitable system could be instituted.

Making Inferences from Controlled Income Maintenance Experiments

By CHARLES E. METCALF*

Since 1968 substantial resources have been devoted to the design and execution of controlled income maintenance experiments.[1] In the typical experiment, a sample of low income households is placed on a variety of negative income tax (*NIT*) plans for a three-year period. The primary objective of these experiments has been to measure 1) the effect of *NIT* on work incentives and 2) the cost of adopting such a welfare scheme nationally.

This paper addresses a question whose answer is essential for interpreting the results of such experiments. If an experiment of limited duration is conducted under "ideal" conditions, what can be inferred from the experimental results about behavior in a world where *NIT* is adopted permanently? By ideal conditions, we mean that (a) individuals (or households)[2] in the experiment are conventional utility maximizers, given the structure of the experiment, and (b) the experiment is sufficiently well designed to permit the differential responses of individuals to be identified.[3] The discussion is limited to a partial equilibrium analysis of an individual's supply of labor (demand for leisure).

Section I extends the usual one-period, static analysis of *NIT* to a multiperiod framework where the effects of a temporary and a permanent *NIT* can be compared. It is shown that, compared to a permanently adopted program, a limited-duration experiment will 1) understate the income effect and 2) overstate the gross and compensated price effects of the *NIT*. Section II analyzes how inferences about behavior under a permanent *NIT* may be drawn from a temporary experiment, and describes how results derived from a two-good, two-period model can be extended to a multigood, multiperiod case. Section III briefly interprets the results outside the context of income maintenance experimentation and outlines some mitigating complications which could affect the results presented in this paper.

I

Consider a one-period model in which a well-behaved function $U(C, L)$ represents the maximum utility an individual may obtain from C dollars of goods purchases and L hours of leisure.[4] The individual takes as given a nonwage income of G dollars, an available quantity of time $\overline{L}$, a wage rate W, and all goods prices. He is assumed to maximize $U(C, L)$ subject to the constraint that $[G+W(\overline{L}-L)-C]$ be nonnegative, i.e., he allocates his consumption between goods and leisure by choosing the quantity of labor he will supply.

* Staff member of the Institute for Research on Poverty and associate professor of economics at the University of Wisconsin. The research reported here was supported by funds granted to the Institute by the Office of Economic Opportunity pursuant to the provisions of the Economic Opportunity Act of 1964. I wish to thank Glen Cain, Robert Haveman, Donald Hester, and Walter Nicholson for their comments on various drafts of this paper. Valuable comments were also received from participants in seminars sponsored by the Institute for Research on Poverty and the Social Systems Research Institute. The conclusions are my responsibility.

[1] In addition to the New Jersey-Pennsylvania Graduated Work Incentive Experiment and the Rural Graduated Work Incentive Experiment (Iowa-North Carolina) funded through the Office of Economic Opportunity, similar experiments are operating in Denver, Gary, and Seattle.

[2] The terms individual and household are used interchangeably in this paper. The household is assumed to possess a single decision maker and to have a finite lifetime corresponding to that of the decision maker.

[3] We are abstracting from all problems related to sample design and stochastic estimation. The analysis of this paper is done in a nonstochastic framework. For a discussion of sample design procedures in such experiments, see Guy Orcutt and Alice Orcutt, and John Conlisk and Harold Watts.

[4] By leisure we mean any nonmarket use of time by the household.

The *NIT* ordinarily provides a household with a fixed income guarantee and simultaneously taxes other income sources of the household at a positive rate up to a "break-even" point where the amount of the guarantee is exhausted. In this model, the *NIT* is assumed to increase nonwage income ($dG>0$) and, through an increase in the tax rate, to decrease the (net of tax) wage rate ($dW<0$).[5] The household is assumed to be below the break-even point, such that its net transfer payment is positive (i.e., $dG+(\bar{L}-L)dW>0$). This latter condition guarantees that the income effect of the guarantee dominates the income effect of the reduction in the wage rate. With a binding budget constraint and the absence of corner solutions (assumed throughout the paper), the imposition of *NIT* increases the demand for leisure through the net income effect if leisure is a normal good. Through the remaining substitution effect, a decline in the wage rate further increases the demand for leisure. Thus, if leisure is a normal good, the *NIT* unambiguously increases the demand for leisure, compared to a situation where no such program is in effect.

In order to compare the effects of a temporary and a permanent *NIT*, the above analysis must be extended to a multiperiod framework. For this exposition consider a two-period, intertemporally additive utility function of the form

$$V = U^1(C_1, L_1) + U^2(C_2, L_2), \tag{1}$$

where the first period coincides with the duration of the temporary *NIT* examined below, and the second corresponds to the remaining lifetime of the individual. The form of $U^1(\cdot)$ and $U^2(\cdot)$ may differ; $U^2(\cdot)$ includes whatever subjective discount factor the individual applies to his future consumption stream.[6] Since the two time periods may be of unequal duration, it should be stressed that G_i, C_i, and L_i ($i=1, 2$) are flows, not aggregates for the time periods in question. The individual maximizes (1) subject to the income constraint

$$\begin{aligned}&[G_1 + W_1(\bar{L} - L_1) - C_1] \\ &\qquad + R[G_2 + W_2(\bar{L} - L_2) - C_2] \geqq 0\end{aligned} \tag{2}$$

where R is the rate at which consumption flows can be transformed from the future to the present. The rate R corresponds to $(1+r)^{-1}$, where r is the one period market rate of interest, if and only if the periods are of equal duration. As period two lengthens relative to period one, R rises to compensate for differences in the time scales; it no longer has a trivial interpretation as an interest rate. If the individual's lifetime is N times the length of period one,[7] and if period two is viewed as N−1 discrete periods each equal to period one in length, then R can be calculated by the formula

$$\begin{aligned}R &= \sum_{i=2}^{N} (1 + r)^{1-i} \\ &= \left[\frac{1 - (1 + r)^{1-N}}{r}\right]\end{aligned} \tag{3}$$

The importance of being able to evaluate R is discussed in Section II.

The conditions for maximizing utility over the two periods are:

$$\begin{aligned} U_C^1 - \lambda &= 0 \\ U_C^2 - \lambda R &= 0 \\ U_L^1 - \lambda W_1 &= 0 \\ U_L^2 - \lambda R W_2 &= 0 \\ [G_1 + W_1(\bar{L} - L_1) &- C_1] \\ + R[G_2 + W_2(\bar{L} - L_2) &- C_2] = 0 \end{aligned} \tag{4}$$

and

$$|H^*| > 0 \tag{5}$$

[5] For expositional purposes, the income guarantee is treated as the only source of nonwage income.

[6] The intertemporal additivity assumption is exploited below in the analysis of substitution effects. It is not required for the results related to income effects. It should also be noted that the individual is assumed to have no bequest motive; he derives utility only from his own consumption.

[7] We can interpret the individual's lifetime as being that portion of his life commencing with the initiation of the *NIT*. Given the form of (1), behavior prior to period one affects behavior during the period of analysis *only* through its effect on the budget constraint.

where $|H^*|$ is the determinant of the relevant Hessian matrix.

A temporary *NIT*, effective during period one, can now be compared with a permanent *NIT*, in force throughout the individual's life. The individual is assumed to know the duration of the *NIT* in each instance, as well as all other relevant information about the future.

The effects of a temporary *NIT* can be derived by changing the values of G_1 and W_1. By differentiating (4) we obtain the effect of a temporary *NIT* upon the first period demand for leisure time.

$$\frac{\partial L_1}{\partial G_1} = \frac{-(W_1 \overset{1}{U}_{CC} - \overset{1}{U}_{LC}) \cdot |D_2|}{|H^*|} \tag{6}$$

and

$$-\frac{\partial L_1}{\partial W_1} = -(\bar{L} - L_1)\frac{\partial L_1}{\partial G_1} - \frac{\lambda}{|H^*|} \cdot [(\overset{1}{U}_{CC} \cdot |J_2|) - |D_2|] \tag{7}$$

where $|D_j|$ is the determinant of the unbordered matrix of second derivatives of $U^j(\cdot)$, and $|J_j|$ is the determinant of the bordered Hessian associated with $|D_j|$.[8] What must be ascertained is whether or not the magnitudes of $(\partial L_1/\partial G_1)$ and the income and substitution components of $(\partial L_1/\partial W_1)$ are unbiased estimates of the magnitudes associated with a permanent change in G and W.

We now differentiate (4) with respect to G and W, where $dG_i = dG$ and $dW_i = dW$, for $i = 1, 2$.

$$\frac{\partial L_1}{\partial G} = (1 + R)\frac{\partial L_1}{\partial G_1} \tag{8}$$

$$\begin{aligned} -\frac{\partial L_1}{\partial W} = &-[(\bar{L} - L_1) + R(\bar{L} - L_2)]\frac{\partial L_1}{\partial G_1} \\ &- \frac{\lambda}{|H^*|}[(\overset{1}{U}_{CC}|J_2|) - |D_2|] \\ &- \frac{\lambda R^2}{|H^*|}(W_1 \overset{1}{U}_{CC} - \overset{1}{U}_{LC}) \\ &\cdot (W_2 \overset{2}{U}_{CC} - \overset{2}{U}_{CL}) \end{aligned} \tag{9}$$

Equation (8) shows the familiar result that consumption is less affected by a transitory change in income than by a permanent change. Evaluated locally, the income effect of a permanent *NIT* is $(1+R)$ times as large as the income effect of a temporary *NIT*. Substituting equation (7) into (9) and simplifying yields:

$$\begin{aligned} -\frac{\partial L_1}{\partial W} = &-\frac{\partial L_1}{\partial W_1} - R(\bar{L} - L_2)\frac{\partial L_1}{\partial G_1} \\ &- \frac{\lambda R^2}{|H^*|}(W_1 \overset{1}{U}_{CC} - \overset{1}{U}_{LC}) \\ &\cdot (W_2 \overset{2}{U}_{CC} - \overset{2}{U}_{CL}) \end{aligned} \tag{10}$$

The final two terms of equation (10) show that the difference in price effects has *both* income and substitution components. If leisure is a normal good, the effect of a reduction in the wage rate on the demand for leisure, estimated in a temporary *NIT* experiment, will typically overstate the permanent price effect for two reasons. First, the estimated negative influence of the income-effect component is biased toward zero. The income effect biases associated with changes in G and W are identical if, and only if, leisure consumption is the same in both periods. Second, the final term in (10) measures the difference between the permanent and transitory substitution effects and will typically be negative.[9]

[8] It should be noted that $|H^*| = |J_1| \cdot |D_2| + |J_2| \cdot |D_1| > 0$. The second-order conditions for optimization also imply that $|J_i| > 0$ for all i, and that $|D_j|$ have a nonpositive value for *at most one j*. If $|D_j|$ is positive for *all j*, an increase in the present value of the individual's income stream will increase total expenditures in every time period. If $|D_j|$ is negative for *one j*, an increase in the present value of income will lead to an expenditure *decrease* in all periods except j. (If $|D_j| = 0$ for *one j*, expenditures would increase in period j and remain constant in all other periods.) In this paper it is assumed that $|D_j| > 0$ for all j, *i.e.*, that the aggregate expenditures in each time period, viewed as a composite commodity, be a "normal good." Nothing in this assumption rules out the possibility of inferiority of individual goods in the consumption bundle. This discussion of restrictions placed on the value of $|D_j|$ parallels the treatment of a single period additive utility function in Eugen Slutsky.

[9] Given that λ and $|H^*|$ are positive, the final term

To summarize this section, if leisure is a normal good, temporary *NIT* experiments will yield estimates of the income effect which is *understated* and of both the gross and the compensated price effects which are *overstated*, relative to what would be observed if a permanent *NIT* program were instituted. It should be noted that a directional statement can be made concerning the *bias* in the gross price effect even though the price effect itself is ambiguous in sign.[10]

II

The identification of three sources of bias (one involving G and two involving W) complicates the process of drawing inferences about permanent behavior from a temporary experiment. In order to make correct inferences the *magnitude* of these biases must be determined. Second, in order to measure the biases, the income and substitution effects must be identified. This implies that different (linearly independent) combinations of income guarantee levels must be included in the design of a *NIT* experiment.

A further examination of equations (8)–(10) suggests procedures for measuring the biases in the estimated income and substitution effects.[11] From (8), the value of R must be known in order to infer the permanent income effect from the estimated transitory measure. Equation (3) indicates that R depends both upon the period interest rate facing the individual and upon his time horizon, measured as a multiple of the length of the experiment. Sample calculations of R illustrate the potential severity of the bias. If the household faces a real annual interest rate of 10 percent ($r=.331$ for a 3-year experimental period) and a time horizon of 30 years (N=10), the bias in the income effect alone would be 2.8 times the measured experimental effect. Even if the time horizon is as short as twice the length of the experiment,[12] this bias would be .75 times the measured effect.

A number of techniques for estimating the value of R are available. If the marginal propensity to consume out of permanent income is known, the result that $1/(1+R)$ equals the ratio of the transitory and permanent marginal propensities to consume can be exploited. Alternatively, if the *NIT* experiment were designed to include subsamples which participated in the program for different time spans, R could be measured directly from observed variations in subgroup income responses.[13]

The income effect component of the bias in the gross price effect (equation (10)) is also a multiple of the observed, temporary income effect, but the value of R does not suffice to measure the size of this component. The present discounted quantity of future labor services provided by the individual must be estimated; in addition to specifying an interest rate, we must assert a relationship between his present and future labor force behavior.

The substitution effect bias in equation (10) can be expressed as:[14]

$$(11)\quad \left[\left(-\frac{\partial L_1}{\partial W}\bigg|_{\bar{U}}\right)-\left(-\frac{\partial L_1}{\partial W_1}\bigg|_{\bar{U}}\right)\right]= -\frac{\lambda R^2}{|H^*|}\,(W_1\overset{1}{U}_{CC}-\overset{1}{U}_{LC})\cdot(W_2\overset{2}{U}_{CC}-\overset{2}{U}_{LC})$$

in (10) will be negative so long as $(W_1U^1_{CC}-U^1_{LC})$ and $(W_2U^2_{CC}-U^2_{LC})$ have the same sign. Given the assumption (see fn. 8) that $|D_j|>0$ and the form of equation (6), $\partial L_i/\partial G_1 \gtrless 0$ as $(W_1U^1_{CC}-U^1_{LC})\lesseqgtr 0$. Thus our requirement is that the effect of an income change on current and future leisure consumption be of the same sign.

[10] If leisure is an inferior good, the income effect would still be understated in absolute value. The statement in fn. 9 about the compensated price effect would stand, but the bias in the gross price effect would be ambiguous in sign.

[11] The entire measurement discussion is in terms of the magnitude of locally evaluated partial derivatives. Additional measurement problems associated with the use of local approximations to evaluate the effects of finite parameter changes are not dealt with in this paper.

[12] While many have argued that low income households have very short time horizons, it is not clear that evidence used to support these arguments in fact support the existence of short time horizons as opposed to high discount rates.

[13] This strategy is being followed in the Seattle-Denver income maintenance experiments.

[14] The notation $|_{\bar{U}}$ is adopted to denote a substitution effect, i.e., the response to a price change accompanied by an income compensation just sufficient to hold utility constant.

This bias can be evaluated by observing the substitution effects of a temporary change in the net wage rate on consumption of all goods during the experiment and estimating the marginal share of leisure in future consumption.

A common adding-up condition from neoclassical consumption theory is that the price-weighted sum of substitution effects of a single price change across all goods equals zero. For a change in W_1, the appropriate condition is:

$$(12)\quad \left(-W_1 \frac{\partial L_1}{\partial W_1}\bigg|_{\bar{U}} - \frac{\partial C_1}{\partial W_1}\bigg|_{\bar{U}}\right) + R\left(-W_1 \frac{\partial L_2}{\partial W_1}\bigg|_{\bar{U}} - \frac{\partial C_2}{\partial W_1}\bigg|_{\bar{U}}\right) = 0$$

Note that the restriction is placed on the price-weighted substitution effects summed over *all* time periods; substitution effects over the period of the experiment are *not* required to sum to zero. The deviation of this latter sum, the first term in (12), from zero is directly related to the substitution bias in (11).

After differentiating (4) to obtain compensated price effects, the weighted sum of $-(\partial L_1/\partial W_1)|_{\bar{U}}$ and $-(\partial C_1/\partial W_1)|_{\bar{U}}$ can be written as:

$$(13)\quad \left(-W_1 \frac{\partial L_1}{\partial W_1}\bigg|_{\bar{U}} - \frac{\partial C_1}{\partial W_1}\bigg|_{\bar{U}}\right) = \frac{-\lambda}{|H^*|}\,(W_1 \overset{1}{U}_{CC} - \overset{1}{U}_{CL}\cdot |J_2|)$$

which is positive or negative depending upon whether leisure is a normal or inferior good during the experimental period.

The marginal share of leisure in future consumption is the remaining element needed to quantify the substitution bias. Again differentiating (4), we can write:

$$(14)\quad R\frac{\partial L_2}{\partial G_1} = \frac{-R^2 |D_1| (W_2 \overset{2}{U}_{CC} - \overset{2}{U}_{LC})}{|H^*|}$$

and

$$(15)\quad R\left(\frac{\partial C_2}{\partial G_1} + W_2 \frac{\partial L_2}{\partial G_1}\right) = \frac{|D_1|\cdot|J_2|}{|H^*|}$$

Taking the ratio of (14) to (15) yields:

$$(16)\quad \frac{R\cdot \dfrac{\partial L_1}{\partial G_1}}{R\cdot\left[\dfrac{\partial C_2}{\partial G_1} + W_2\dfrac{\partial L_2}{\partial G_1}\right]} = \frac{-R^2[W_2 \overset{2}{U}_{CC} - \overset{2}{U}_{LC}]}{|J_2|}$$

Note that the substitution bias defined in (11) equals, with a sign change, the *product* of equations (13) and (16). Thus, from equation (17), we see that the bias in the observed substitution effect is the product of two factors: 1) the weighted sum of substitution effects observed during the experimental period and 2) the marginal share of leisure in future consumption. While the R cancels out of the second factor in this two-period case, discounting plays an important role when the future is disaggregated into multiple periods. Then the second factor becomes the ratio of the effect of an income change on the present discounted *quantity* of future leisure to the effect of an income change on the present discounted *value* of future total consumption.[15] Because the numerator and denominator are measured in different units, the ratio differs from a marginal budget share

Evaluation of the substitution bias requires some estimate of future leisure. One approach would be to assume that present and future leisure shares of total consump-

[15] Specifically, the term corresponding to (16) becomes

$$\frac{\sum_i^{2,N} (1+R)^{1-i}\dfrac{\partial L_i}{\partial G_i}}{\sum_i^{2,N} (1+R)^{1-i}\left(\dfrac{\partial C_i}{\partial G_i} + W_i\dfrac{\partial L_i}{\partial G_i}\right)}$$

$$(17)\quad \left[\left(-\frac{\partial L_1}{\partial W}\bigg|_{\bar{U}}\right) - \left(-\frac{\partial L_1}{\partial W_1}\bigg|_{\bar{U}}\right)\right] = -\left(-W\frac{\partial L_1}{\partial W_1}\bigg|_{\bar{U}} - \frac{\partial C_1}{\partial W_1}\bigg|_{\bar{U}}\right)\cdot\left\{\frac{R\dfrac{\partial L_2}{\partial G_1}}{R\left(\dfrac{\partial C_2}{\partial G_1} + W\dfrac{\partial L_2}{\partial G_1}\right)}\right\}$$

tion are identical at the margin. Given the assumptions underlying this model, an error in the estimated value of the ratio in (17) translates into an equal percentage error in the estimated substitution bias.[16]

The results of this paper can easily be extended to a model with m goods. The reported results concerning income effects can be generalized directly to the multigood case. The biases in the substitution effects of a price change on any two goods can be shown to be proportional to the effects of an income change on consumption of the two goods.[17] If present and future consumption shares (defined as in (16)) are the same for the good undergoing the price change, the price-weighted sum of substitution biases corresponds directly to deviation of the observed sum of substitution effects from zero. Similarly, the results can be reproduced with a multiperiod model in which the form of $U^i(\cdot)$ is again permitted to vary across periods. At each point in the above discussion where future behavior plays a role, the multiperiod analog involves a present discounted quantity or value.

III

The preceding analysis shows how inferences about permanent behavioral relationships can be drawn from measurements of behavior observed in a temporary experiment. The converse problem exists in many discussions of the use of fiscal instruments. Policy makers may wish to predict the effect of temporary fiscal measures from observed empirical effects of earlier fiscal measures which were considered to be permanent. Examples of such instruments would include the 1968 Income Tax Surcharge, temporary investment tax credits, and import surcharges. This paper suggests procedures for analyzing the strength of such fiscal measures; but since it is a partial equilibrium analysis, these procedures are not necessarily reliable for making predictions about the general equilibrium or macro-economic magnitude of their effects.

Several assumptions were employed in the above analysis in order to obtain the reported results. First, the discussion of substitution biases appears to hinge on the assumption that preferences are intertemporally additive. Second, durable and storable goods were excluded from consideration. Third, the households were assumed to be price takers and face perfect capital and labor markets. The nature and degree of imperfection in loan and labor markets serving low income households should be investigated before we either interpret the results of current *NIT* experiments or apply to those results the measures of bias described here. Fourth, households were assumed to adjust instantaneously and costlessly to changes in their economic environment. Again, the magnitude of real world adjustment costs and lags must be investigated. Finally, households were assumed to behave as if they knew the duration of the experiment with certainty. Since this assumption may be violated, and since an experiment may create expectations that *NIT* may be permanently adopted, the effects of uncertainty and of different patterns of expectations on behavior must be examined.

[16] Since consumption patterns in the distant future are discounted heavily, the fact that relative leisure consumption increases substantially after an individual reaches retirement age does not have a major impact on the appropriateness of using current leisure behavior as an approximation of discounted future behavior.

[17] The close relationship between substitution and income effects has its origins in the assumption of intertemporal additivity. For a general discussion of additive preferences, see Hendrik Houthakker.

The Production Function and the Theory of Distributive Shares

By Ryuzo Sato and Tetsunori Koizumi*

One of the stylized facts concerning the performance of an aggregate economy over the last generation or so has been the constancy of income shares between wages and profits. For some this is nothing but the confirmation of the fact that the underlying production function of the economy is of the Cobb-Douglas type, and for others this is due to a bias in technological change with variable elasticity of substitution between labor and capital.[1] But, regardless of whether one believes in an aggregate production function upon which most of these studies are based, or differs in opinion on factors responsible for it, there is a wide consensus among economists on the stability of macro-distributive shares.

The myth surrounding the constancy of factor shares breaks down once we turn our attention to micro units of the economy—at a firm, an industry, or even a sector level. If the production function, which of course becomes better delineated the further we disaggregate, could be expressed in terms of two factor inputs, it would be easy to explain any observed behavior of factor shares by appealing to a simple relation derived by J. R. Hicks between the elasticity of substitution and factor shares.[2] But a micro-production function, since a finer classification of factor inputs is feasible and the data are easier to come by, is conceivably more meaningfully characterized by the multiplicity of factor inputs. The development in the multifactor case, however, had to wait until 1968 when Paul Samuelson first introduced a simple, yet suggestive, concept of the elasticity of substitution. By considering the substitutability of a factor against all other inputs taken together, he was able to demonstrate that the relative share of a factor increases or decreases as the supply of that factor increases depending on whether his elasticity of substitution is greater or smaller than unity. Thus, the usage of the elasticity of substitution in this particular sense was transferred very smoothly from the two-factor to the multifactor case.

Samuelson's new concept, bold and ingenious as it is, has solved only one specific problem, namely, that of the effect of an increase in the supply of *one* factor upon the relative share of that *same* factor. There are, of course, other equally interesting questions one can ask in the multifactor case. For example, what will be the effect of an increase in the supply of *one* factor upon the relative share of *another* factor? What about the effect of a change in the *intensity* of the usage of two factors upon the *ratio* of relative shares of these factors? What about the effect of an increase in the supply of *one* factor upon the *proportion* of relative share of this factor in the total share of a *group* of factors to which this factor may or may not belong? What if the *price* rather than the *quantity* of a factor changes? Not only are these problems of theoretical interest, they are relevant in that they also appear in the real life context as we shall show below with specific examples.

The purpose of this paper is to suggest elements of a complete theory of distributive shares by deriving the different concepts of the elasticity of substitution required in different contexts. Section I briefly discusses the model of production and distribution in the multifactor case. Section II analyzes the role of the Samuelson elasticity and the partial elasticities. Section III discusses the direct and shadow elasticities. In addition, other elasticities are introduced to analyze

the variety of problems one encounters in real life.

I. The Model

Consider a firm producing output (y) with a n-factor constant returns to scale production function

$$(1) \qquad y = f(x_1, \ldots, x_n)$$

where $x_i = i$th factor input. The function f is assumed to be a concave function with continuous partial derivatives up to, at least, the second order. As dual to the production function (1), we have the unit cost function

$$(2) \qquad c = g(p_1, \ldots, p_n)$$

which is a linear homogeneous, concave function in prices (p_i = price of the ith input). Because of this perfect symmetry between production and cost functions, known as the duality theory, plus the equality between total revenue and total cost which is the equilibrium condition of a firm under pure competition, the subsequent argument on the relationship between the elasticity of substitution and the behavior of factor shares can be conducted in terms of both production and cost functions.

Under competitive conditions, the relative share of factor x_i is given by

$$(3) \qquad \alpha_i = \frac{f_i x_i}{f} = \frac{g_i p_i}{g}, \quad (1 \le i \le n)$$

$$f_i = \frac{\partial f}{\partial x_i}, \quad g_i = \frac{\partial g}{\partial p_i}, \quad \sum_{i=1}^{n} \alpha_i = 1$$

Thus, the relative share can be expressed in two alternative ways either as the proportion of output paid to factor x_i relative to the total output or as the proportion of expenditure on x_i relative to the total cost of production. This enables us to analyze not only the "direct" effect on factor shares of a change in the quantity of a factor via the change in marginal product but also the "indirect" effect of a change in the price of a factor via the change in quantity demanded of that factor.[3]

[3] This is due to the fact that the marginal effect on unit cost of a change in factor price p_i is equal to the quantity demanded of factor i, i.e., $g_i = x_i$.

II. Effects on the Size of Relative Factor Shares

It would be useful to start with a concrete example in order to bring home the empirical relevance of the subsequent analysis. Suppose that the firm under consideration employs two classes of laborers—black and white—in addition to other factor inputs, and that it decides to employ one additional black laborer to fill the job vacancy. How will this affect the relative share of the black laborers? What about its effect on the share of white laborers? In this section, we examine the elasticity concepts required to answer these questions.

Samuelson Elasticity

First consider the effect of an increase in the quantity of *one* factor (black laborer) upon the size of the relative share of *that* factor (black laborer). This is the problem investigated by Samuelson and the result can be stated as: *the relative share of one factor increases or decreases as the quantity of that factor increases depending on whether the "Samuelson" elasticity of substitution is greater or smaller than unity, i.e.,*

$$(4a) \quad sgn\left(\frac{\partial \alpha_i}{\partial x_i}\right) \gtreqless 0 \text{ according as } \sigma_i \gtreqless 1,$$

where

$$(5a) \qquad \sigma_i = \frac{-(1-\alpha_i)f_i}{f_{ii}x_i}$$

is the *Samuelson elasticity of substitution* of factor x_i.

By the aforementioned duality theorem, we can formulate the dual problem to (4a) which is concerned about the effect of an increase in the price of x_i on α_i. The result is given by

$$(4b) \quad sgn\left(\frac{\partial \alpha_i}{\partial p_i}\right) \gtreqless 0 \text{ according as } \sigma_i^d \gtreqless 1$$

where σ_i^d is formally defined as

$$(5b) \qquad \sigma_i^d = \frac{-(1-\alpha_i)g_i}{g_{ii}p_i}$$

We may call σ_i^d in (5b) the "*dual*" *Samuelson*

elasticity of substitution of factor x_i, for it is the exact dual of σ_i in (5a) in that it is defined in terms of the unit cost function (2) which is dual to the production function (1). Thus, (4b) says: *the relative share of one factor increases or decreases as the price of that factor increases depending on whether the "dual" Samuelson elasticity of substitution is greater or smaller than unity.*

Partial Elasticity

Next consider the effect of a change in the quantity (or price) of *one* factor (black laborer) upon the relative share of *another* factor (white laborer). Although the problem seems to be a slight variant of the one just discussed, it turns out that the Samuelson elasticity will not be of much help in answering it. Fortunately for us, however, a rather celebrated "partial" elasticity concept comes to the rescue. The results can be stated as: *the relative share of one factor increases or decreases as the quantity (price) of another factor increases depending on whether the partial elasticity of complementarity (substitution) between the two factors in question is greater or smaller than unity, i.e.,*

$$sgn\left(\frac{\partial\alpha_i}{\partial x_j}\right) \gtreqless 0 \quad \text{according as } c_{ij} \gtreqless 1, \qquad (i \neq j) \tag{6a}$$

$$sgn\left(\frac{\partial\alpha_i}{\partial p_j}\right) \gtreqless 0 \quad \text{according as } \sigma_{ij} \gtreqless 1, \qquad (i \neq j) \tag{6b}$$

where

$$c_{ij} = \frac{ff_{ij}}{f_if_j}, \qquad (i \neq j) \tag{7a}$$

is the *partial elasticity of complementarity* and

$$\sigma_{ij} = \frac{gg_{ij}}{g_ig_j}, \qquad (i \neq j) \tag{7b}$$

is the *partial elasticity of substitution* between x_i and x_j.[4]

Noting that both c_{ij} and σ_{ij} can be either positive or negative (which determines whether x_i and x_j are substitutes or complements),[5] the results in (6a) and (6b) indicate that it is the degree of substitutability which is crucial in determining the behavior of factor shares. For example, suppose that the black and white laborers are strong substitutes, i.e., the partial elasticity of substitution between them is greater than unity. An increase in the wage of white laborers induces the substitution of black laborers for white laborers. An increase in demand for the black laborers thus generated means an increased payment to the black laborers in the total factor payments, thus leading to an increase in the relative share of the black laborers. When the black and white laborers are complementary (i.e., $\sigma_{ij}<0$), an increase in the wage of white laborers always decreases the relative share of black laborers.[6]

III. Effects on the Ratio of Relative Factor Shares

In the previous section we analyzed the effect of a change in the quantity or price of a factor on the size of factor shares. But in the presence of multiple factors equally interesting questions can be asked about the effects on the various ratios of factor shares. Thus, supposing that there is an increase in

[4] The definition of the partial elasticity of "complementarity" is found in Sato and Koizumi (1971) in view of the suggestions due to Hicks (1970). It is the dual concept to the well-known definition of the Allen partial elasticity of substitution.

[5] Two factors x_i and x_j are said to be q-complements or q-substitutes according as c_{ij} is positive or negative, and p-substitutes or p-complements according as σ_{ij} is positive or negative. See Hicks (1970) and Sato and Koizumi (1971).

[6] It is to be noted that the results in (4) and (6) are not totally independent from each other, for the Samuelson elasticity and partial elasticity are related in a certain manner due to the linear homogeneity of f and g functions. To be exact, the relations are

$$1/\sigma_i = \frac{1}{1-\alpha_i}\sum_{j\neq i}\alpha_jc_{ij} \quad \text{and} \quad 1/\sigma_i^d = \frac{1}{1-\alpha_i}\sum_{j\neq i}\alpha_j\sigma_{ij}$$

That is, *the inverse of the Samuelson elasticity of substitution (and that of the dual Samuelson elasticity) of factor x_i is a weighted average of $n-1$ partial elasticities of complementarity (substitution) between x_i and $n-1$ other factor inputs.*

the ratio of black over white laborers, how will this affect the ratio of factor shares between these two classes of laborers? Or one may well conceive of a firm which employs three classes of laborers—black, white, and brown. Then, supposing that a firm decides to increase the use of brown laborers, how will this affect the relative income position of one class of laborers against other classes of laborers? Extending the argument in this manner, one may in general ask about the effect on the ratio of factor shares between two groups of factor inputs. The concepts introduced in the previous section will not help to answer these questions. Hence, we have to develop the elasticity concepts necessary to analyze this type of problem.

Direct and Shadow Elasticities

The simplest case that falls under the present category is the effect of a change in the relative intensity (or relative price) of two factors upon the ratio of factor shares of these factors. As was already pointed out, no new elasticity concept is needed in this case if there are only two factor inputs. In the multifactor case, the results turn out to depend on two other rather celebrated elasticity concepts. That is,

$$\text{(8a)} \quad sgn \frac{\partial\left(\dfrac{\alpha_i}{\alpha_j}\right)}{\partial\left(\dfrac{x_i}{x_j}\right)} \gtreqless 0 \quad \text{according as } d_{ij} \gtreqless 1$$

$$\text{(8b)} \quad sgn \frac{\partial\left(\dfrac{\alpha_i}{\alpha_j}\right)}{\partial\left(\dfrac{p_i}{p_j}\right)} \gtreqless 0 \quad \text{according as } s_{ij} \gtreqless 1$$

where

$$\text{(9a)} \quad d_{ij} = \frac{\partial \log (x_i/x_j)}{\partial \log (f_j/f_i)}, \qquad i \neq j$$

is the *direct elasticity of substitution* between x_i and x_j and

$$\text{(9b)} \quad s_{ij} = \frac{\partial \log (p_i/p_j)}{\partial \log (g_j/g_i)}, \qquad i \neq j$$

is the *shadow elasticity of substitution* between x_i and x_j.[7]

Composite Elasticities

We shall next develop the elasticity concept required to analyze the effect of a change in the quantity (or price) of brown laborers on the *relative income position* of brown laborers against black and white laborers. Let subscripts i, j, and k stand for brown, black, and white laborers, respectively. The income position of brown laborers relative to black and white laborers can be measured by $\alpha_i/(\alpha_j+\alpha_k)$ or its inverse. As the quantity (or price) of brown laborers changes, their relative income position changes as

$$\text{(10a)} \quad sgn \frac{\partial\left(\dfrac{\alpha_j+\alpha_k}{\alpha_i}\right)}{\partial x_i} \gtreqless 0 \quad \text{according as } \psi_i \gtreqless 1$$

$$\text{(10b)} \quad sgn \frac{\partial\left(\dfrac{\alpha_j+\alpha_k}{\alpha_i}\right)}{\partial p_i} \gtreqless 0 \quad \text{according as } \phi_i \gtreqless 1$$

where ψ_i and ϕ_i are the desired elasticities we are looking for. Let us define these elasticities as the *composite elasticities of substitution* of factor i. Formally they are defined as

$$\text{(11a)} \quad \psi_i = (1-\alpha_i)\frac{1}{\sigma_i} + \alpha_i c_i$$

$$\text{(11b)} \quad \phi_i = (1-\alpha_i)\frac{1}{\sigma_i^d} + \alpha_i d_i$$

where

$$c_i = \frac{\alpha_j}{\alpha_j+\alpha_k} c_{ji} + \frac{\alpha_k}{\alpha_j+\alpha_k} c_{ki}$$

[7] The direct elasticity concept is a straightforward extension of the original Joan Robinson definition. The shadow elasticity is due to Daniel McFadden.

TABLE 1—SUMMARY OF ELASTICITY CONCEPTS

Effects on	Changes in x_i	p_i	x_j	p_j	x_i/x_j	p_i/p_j
α_i	Samuelson	Dual Samuelson	Partial elasticity of complementarity	Partial elasticity of substitution		
α_i/α_j					Direct	Shadow
$(\alpha_j+\alpha_k)/(\alpha_i)$	Composite	Dual composite				
$\Sigma\alpha_s/\Sigma\alpha_t$	Group elasticity of complementarity	Group elasticity of substitution				

and[8]

$$d_i = \frac{\alpha_j}{\alpha_j + \alpha_k}\sigma_{ji} + \frac{\alpha_k}{\alpha_j + \alpha_k}\sigma_{ki}.$$

Thus, ψ_i for example is a *convex* combination of the inverse of the Samuelson elasticity and the weighted average of partial elasticities of complementarity between x_i and x_j and between x_i and x_k. Returning to the example of brown versus black and white laborers, the results in (10) indicate that the *increase in the supply of brown laborers is more favorable to their relative income position, the greater is the Samuelson elasticity of substitution of brown laborers against all other factor inputs and/or the smaller are the partial elasticities of complementarity between brown and black and between brown and white laborers.*

Group Elasticities

The composite elasticities discussed above are useful in analyzing the relative income position of one factor against a group of factor inputs. We can, of course, generalize this problem to the comparison of income shares of two groups of factor inputs. Thus, for example, one group of factors may be the workers consisting of black, white, and brown laborers and another group the management consisting of presidents, executives, and branch managers. Supposing that a firm decides to adopt new and efficient capital equipment, how will this affect the relative income positions of these two groups of people? Formally, the results can be stated as

$$\text{(12a)}\quad sgn\,\frac{\partial\left(\sum_{s\in I}\alpha_s \Big/ \sum_{t\in J}\alpha_t\right)}{\partial x_k} \gtreqless 0 \quad \text{according as } C_I - C_J \gtreqless 0$$

$$\text{(12b)}\quad sgn\,\frac{\partial\left(\sum_{s\in I}\alpha_s \Big/ \sum_{t\in J}\alpha_t\right)}{\partial p_k} \gtreqless 0 \quad \text{according as } D_I - D_J \gtreqless 0,$$

where I and J are any two nonintersecting subsets of n factors of production and C_I and C_J are the weighted averages of the partial elasticities of complementarity of group I and J, respectively, and similarly for D_I and D_J with the partial elasticities of substitution. Thus, which group is more favorably affected depends on the relative magnitude of these group elasticities. We may define C_I and D_I as the *group elasticities*

[8] The reader may verify that the same elasticity ψ_i also determines the sign of $\partial[(\alpha_i+\alpha_j+\alpha_k)/\alpha_i]/\partial x_i$. In principle, the composite elasticity could be extended to include more factors. Thus, we may talk about the composite elasticity of brown laborers against black, white, and grey laborers, say, and so on. There is, however, an upper bound on the number of factors to be included. To be exact, that number is $n-2$, for if it is $n-1$ then we would be comparing the income share of one factor against those of all other factors (i.e., α_i versus $1-\alpha_i$) and the relevant elasticity for this problem reduces to the Samuelson elasticity.

of complementarity and substitution of factor group I.[9]

The results we obtained above are schematically summarized in Table 1. It is suggested that the reader fill the remaining blanks with appropriate concepts which will be hybrids of the concepts discussed above.

[9] The results in (10) and (12) are easily obtained by logarithmic differentiation

$$\frac{\partial \log\left(\dfrac{\alpha_j + \alpha_k}{\alpha_i}\right)}{\partial \log x_i} = (1 - \alpha_i)\frac{1}{\sigma_i} + \alpha_i\left(\frac{\alpha_j}{\alpha_j + \alpha_k}c_{ji} + \frac{\alpha_k}{\alpha_j + \alpha_k}c_{ki}\right) - 1$$

and

$$\frac{\partial \log\left(\sum_{s\in I}\alpha_s \Big/ \sum_{t\in J}\alpha_t\right)}{\partial \log x_k} = \alpha_k(C_I - C_J)$$

where C_I, for example, looks like

$$C_I = \frac{\alpha_i}{\alpha_i + \alpha_j + \alpha_l}c_{ik} + \frac{\alpha_j}{\alpha_i + \alpha_j + \alpha_l}c_{jk} + \frac{\alpha_l}{\alpha_i + \alpha_j + \alpha_l}c_{lk}$$

for $I = (i, j, l)$

The Neoclassical Theory of Technical Progress: Note

By J. BOHMAN AND M. K. BOHMAN*

In his article on technical progress in this *Review*, Winston Chang presents " . . . the asymmetrical results out of Harrod's and Solow's classifications [of bias] in relation to that of Hicks" (p. 913) for a two-sector model. He also shows " . . . that the usual symmetrical results obtained for aggregate neutrality between the Hicksian and Harrodian schema, . . . in general, do not apply to Solow-neutrality" (p. 913). This note demonstrates that the asymmetries to which Chang refers result from the manner in which he defines the Solow measure of bias in the capital-goods sector. If this measure is redefined, the asymmetries vanish.

Chang defines the Solow parameter, u_{Lj}, $(j=1, 2)$, as the proportional rate of reduction in the labor-output ratio in sector j at a constant wage rate (pp. 913, 918): $u_{Lj} \equiv e_{Lj}|_{\hat{w}=0}$, where $e_{Lj} \equiv (\hat{Y}_j - \hat{L}_j)$; Y_j is the output of sector j, L_j is labor employed in sector j, $(\hat{\ })$ over a variable represents the relative change in that variable, and w is the wage rate measured in terms of the consumption good.[1] It follows that the labor-output ratio under consideration in sector 1 is labor per unit of capital good (L_1/Y_1) whereas the corresponding ratio in sector 2 is labor per unit of consumption good (L_2/Y_2). Chang defines the Solow measure of bias in sector j as $\gamma_j \equiv (1/\theta_{Kj})u_{Lj}$, where θ_{Kj} $(0<\theta_{Kj}<1)$ is the share of capital in sector j.

I. Redefining the Solow Measure of Bias

State the labor-output ratio in sector 1 in terms of consumption goods (L_1/pY_1), where p is the price of a capital good measured in consumption goods. It follows that both the labor-output ratios in sectors 1 and 2 and the wage rate are stated in terms of the consumption good. Denote the proportionate rate of reduction in the labor-output ratios by $\overset{v}{e}_{Lj}$. From the definition of e_{Lj}, it is clear that

$$(1)\qquad \overset{v}{e}_{L1} = \hat{Y}_1 - \hat{L}_1 + \hat{p} = e_{L1} + \hat{p}$$
$$\overset{v}{e}_{L2} = e_{L2}$$

Substitution of Chang's equations (8), (23), and (29) into our equation (1) yields:

$$(2)\qquad \overset{v}{e}_{L1} = (\sigma_1\theta_{K1}/\theta_{K2} + 1 - \theta_{K1}/\theta_{K2})\hat{w} + \theta_{K1}(1-\sigma_1)T_{K2} + \theta_{K1}\beta_1$$

where σ_j, T_{Kj}, and β_j denote the elasticity of factor substitution, the Solow rate of progress, and the Hicks measure of bias, respectively, in sector j. Define the Solow measure of bias, $\bar{\gamma}_j$, such that $\bar{\gamma}_j \equiv (1/\theta_{Kj})\overset{v}{e}_{Lj}|_{\hat{w}=0}$. From our equation (2) and Chang's equation (42), it follows that[2]

$$(3)\qquad \bar{\gamma}_j = \beta_j + (1-\sigma_j)T_{K2}$$

which gives the relationship between the Solow and Hicks measures of bias.[3]

II. Implications

From our equation (3), it follows that Hicks neutrality is equivalent to Solow neutrality in sector j if the elasticity of factor substitution in j equals unity.[4] This result is

[2] γ_j denotes Chang's definition of the measure of Solow bias; $\bar{\gamma}_j$ denotes our definition of that measure. Since no modifications with respect to the consumption-goods sector have been made, $\gamma_2=\bar{\gamma}_2$.

[3] The foregoing procedure of redefining the Solow measure of bias parallels Chang's development of the Harrod measure of bias (pp. 916–17). In the latter case, the capital-output ratio in sector 1 is measured in terms of the capital good. His equation (28), $\overset{*}{e}_{K2}=e_{K2}-\hat{p}$, where $e_{K2}=(\hat{Y}_2-\hat{K}_2)$ and K_2 is the capital employed in sector 2, implies that the relevant capital-output ratio in sector 2 $[pK_2/Y_2=K_2/(Y_2/p)]$ is stated in terms of the capital good. Hence, both the capital-output ratios in each sector and the rate of profit are measured in terms of the capital good.

[4] The above statement holds for sector 2 in Chang's analysis but not for sector 1; see his equation (45).

* University of Santa Clara.

[1] Sector 1 $(j=1)$ is the capital-goods sector; sector 2 $(j=2)$ is the consumption-goods sector.

symmetrical to that of Chang's equation (34) which establishes the relationship between the Harrod and Hicks measures of bias; in particular, the Hicks and Harrod neutralities are equivalent in j if the elasticity of factor substitution in j equals unity.[5] If no progress occurs in sector 2, Hicks neutrality and Solow neutrality are equivalent in sector 1. Contrary to Chang's findings, this result is "... symmetrical to Kennedy's result (1962a, 1962b) concerning the equivalence of Hicks and Harrod neutrality in the consumption-goods sector when there is no progress in the other sector" (p. 919).

Substituting Chang's equation (34) into our equation (3) establishes the relationship between the Harrod and Solow measures of bias:

$$(4) \qquad \bar{\gamma}_j = \alpha_j + (1 - \sigma_j)(T_{L1} + T_{K2})$$

where α_j is the Harrod measure of bias and T_{Lj} is the Harrod rate of progress in sector j. The Solow and Harrod neutralities are equivalent if the elasticity of factor substitution equals unity; hence, if $\sigma_j = 1$, all three classifications of neutrality are equivalent and the production function is Cobb-Douglas.

For the case of Solow own neutrality, define $\bar{\gamma}_1^0 \equiv (1/\theta_{K1})e_{L1}^v|_{\hat{w}-\hat{p}=0}$ and $\bar{\gamma}_2^0 \equiv (1/\theta_{K2})e_{L2}^v|_{\hat{w}=0}$. Clearly, $\bar{\gamma}_2 = \bar{\gamma}_2^0$; hence, substituting Chang's equations (8), (21), and (29) into our equation (1) yields:

$$(5) \qquad \bar{\gamma}_j^0 = \beta_j + (1 - \sigma_j)T_{Kj} + (\theta_{K2}/\theta_{K1})(T_{K2} - T_{Kj})$$

In sector 2, Solow own neutrality is equivalent to Hicks neutrality (or own neutrality) if $\sigma_2 = 1$;[6] on the other hand, in sector 1, the two are equivalent if $\sigma_1 = 1$ and $T_{K1} = T_{K2}$.[7]

Substituting Chang's equation (41) into our equation (5) yields:

$$(6) \qquad \bar{\gamma}_j^0 = \alpha_j^0 + (1 - \sigma_j)(T_{Lj} + T_{Kj}) - (\theta_{L1}/\theta_{L2})(T_{Lj} - T_{L1}) + (\theta_{K2}/\theta_{KI})(T_{K2} - T_{Kj})$$

where θ_{Lj} is labor's share in j and α_j^0 is the Harrod own measure of bias. In sector 1, Harrod own neutrality is equivalent to Solow own neutrality if $\sigma_1 = 1$ and $T_{K1} = T_{K2}$. The same can be said for sector 2 if $\sigma_2 = 1$ and $T_{L1} = T_{L2}$. Both neutralities occur if

$$(7) \qquad \sigma_1 = 1 + (\theta_{K2}/\theta_{K1})(T_{K2} - T_{K1}) \cdot (T_{L1} + T_{K1})^{-1}$$

and[8]

$$\sigma_2 = 1 + (\theta_{L1}/\theta_{L2})(T_{L1} - T_{L2}) \cdot (T_{L2} + T_{K2})^{-1}$$

Following Chang, p. 920, define $\rho \equiv T_{L1}/(T_{L1}+T_{K2})$, where $0 \leqq \rho \leqq 1$. Using Chang's equation (34) and our equation (4), eliminate σ_j. The result is[9]

$$(8) \qquad \beta_j = \rho\bar{\gamma}_j + (1 - \rho)\alpha_j$$

Several symmetrical results emerge which are not present in Chang's analysis (see p. 920). In both sectors, β_j is a weighted average of the other two measures of bias. If $\rho = 0$ (no progress in sector 1), the Hicks and Harrod measures of bias in sector 2 are equivalent and independent of the Solow measure; if $\rho = 1$ (no progress in sector 2),

[5] Chang's equation (34) is as follows:

$$\alpha_j = \beta_j - (1 - \sigma_j)T_{L1}$$

where α_j and T_{Lj} are the Harrod measure of bias and the Harrod rate of progress, respectively, in sector j.

[6] Hicks neutral and Hicks own neutral are the same; see Chang, p. 918, fn. 23.

[7] Contrast this with Chang's equation (48), $\gamma_j^0 = \beta_j + (1-\sigma_j)T_{Kj}$, which indicates that Hicks neutrality and Solow own neutrality are equivalent if $\sigma_j = 1$. Note the symmetry between the results of our equation (5) and that of Chang's equation (41). For the latter, Harrod own neutrality is equivalent to Hicks neutrality in sector 1 if $\sigma_1 = 1$ and in sector 2 if $\sigma_2 = 1$ and $T_{L2} = T_{L1}$.

[8] Compare (6) with Chang's equation (49). In his analysis, the two neutralities are equivalent in sector 1 if $\sigma_1 = 1$; they are equivalent in sector 2 if $\sigma_2 = 1$ and $T_{L1} = T_{L2}$. Both occur if $\sigma_1 = 1$ and

$$\sigma_2 = 1 + (\theta_{L1}/T_{K2})(T_{L1} - T_{L2});$$

see Chang, p. 919.

[9] The corresponding equation in Chang's analysis is his equation (50), $\beta_j = \rho\gamma_j + (1-\rho)\alpha_j + \rho(T_{K2} - T_{Kj})$.

the Hicks and Solow measures in sector 1 are equivalent and independent of Harrod's measure. If progress occurs in both sectors ($0<\rho<1$), then for each sector any two neutralities imply the neutrality of the third.

If Solow (Harrod) neutrality prevails in sector 2 (sector 1), the Hicks classification is equivalent to Harrod's (Solow's).[10] If Harrod (Solow) neutrality prevails in sector 2 (sector 1), Hicks classification, except for the neutrality case, implies the corresponding classification of Solow (Harrod) in that sector, but not vice versa.[11] If Hicks neutrality occurs in sector 1, Solow labor-saving (capital-saving) progress implies Harrod capital-saving (labor-saving) improvement, but not vice versa.[12]

Eliminating σ_j from our equation (5) and Chang's equation (41) yields:

$$(9) \quad \beta_j = \theta_{Kj}\overset{0}{\bar{\gamma}_j} + \theta_{Lj}\overset{0}{\alpha_j} + (\theta_{Lj}\theta_{L1}/\theta_{L2})(T_{L1} - T_{Lj}) + (\theta_{Kj}\theta_{K2}/\theta_{K1})(T_{Kj} - T_{K2})$$

which establishes the relationship among the three measures of own bias.[13] Again several symmetrical results emerge which are not present in Chang's analysis. If the Solow (Harrodian) rates of technical progress between sectors are equal, then: (i) the Hicksian bias in sector 1 (sector 2) is a weighted average of the other two own biases; (ii) any two own neutralities in sector 1 (sector 2) implies the own neutrality of the third; (iii) for sector 1 (sector 2), own neutrality in Harrod's or Solow's sense implies the equivalence of the other two; and (iv) for sector 1 (sector 2), Hicks neutrality implies that Harrod's own labor-saving, neutral, or capital-saving improvement is equivalent to Solow's own capital-saving, neutral, or labor-saving improvement, respectively. If the Solow rate of technical progress in sector 2 is greater (less) than that in sector 1, then for sector 1 (i) Hicks and Harrod own neutrality implies Solow own labor-saving (capital-saving); (ii) Harrod and Solow own neutrality implies Hicks capital-saving (labor-saving); and (iii) Hicks and Solow own neutrality implies Harrod own labor-saving (capital-saving). If the Harrod rate of technical progress in sector 2 is greater (less) than that in sector 1, the same can be said for sector 2.

To reconstruct Chang's formulation of aggregate Solow neutrality, consider his equation (52), p. 921, for the aggregate labor-output ratio:

$$(10) \quad L/Y = \theta_1 L_1/(pY_1) + \theta_2 L_2/Y_2$$

where $L=L_1+L_2$, $Y=pY_1+Y_2$ denotes national income in terms of the consumption good, and θ_j is the share of sector j in Y.

If our equation (4) is substituted for Chang's equation (45), his equation (53) becomes

$$(11) \quad e_L = C_1\hat{w} + C_2 + C_3$$

where

$$C_1 \equiv \lambda_{L2}\sigma_2 + \lambda_{L1}[(\sigma_1 - 1)(\theta_{K1}/\theta_{K2}) + 1]$$
$$C_2 \equiv \lambda_{L1}\theta_{K1}\bar{\gamma}_1 + \lambda_{L2}\theta_{K2}\bar{\gamma}_2$$
$$C_3 \equiv \lambda_{L1}\hat{\theta}_1 + \lambda_{L2}\hat{\theta}_2$$
$$e_L = \hat{Y} - \hat{L}$$
$$\lambda_{Lj} = L_j/L$$

Solow neutrality in each sector ($\bar{\gamma}_1 = \bar{\gamma}_2 = 0$) results in aggregate Solow neutrality ($e_L|_{\hat{w}=0} = 0$) if, and only if, $C_3|_{\hat{w}=0} = 0$. Since, p. 922,

$$(12) \quad \hat{\theta}_1 = \theta_2(1 - \sigma_D)\hat{p}$$
$$\hat{\theta}_2 = -\theta_1(1 - \sigma_D)\hat{p}$$
$$\hat{p}|_{\hat{w}=0} = \theta_{K1}(T_{K2} - T_{K1})$$

it follows that

$$(13) \quad C_3|_{\hat{w}=0} = \theta_{K1}(1 - \sigma_D)(T_{K2} - T_{K1}) \cdot (\lambda_{L2}\theta_1 - \lambda_{L1}\theta_2)$$

[10] In this case, $T_{K2}>0$, $0\leqq\rho<1$, and $\beta_2=(1-\rho)\alpha_2$. For the parenthetical case, $T_{L1}>0$, $0<\rho\leqq 1$, and $\beta_1=\rho\bar{\gamma}_1$.

[11] In this case, $\beta_2=\rho\bar{\gamma}_2$ and $0\leqq\rho<1$. For the parenthetical case, $\beta_1=(1-\rho)\alpha_1$ and $0<\rho\leqq 1$.

[12] The corresponding statement for the other sector is: "... if progress is Hicks-neutral in sector 2, Harrod labor-saving (capital-saving) progress necessarily implies Solow capital-saving (labor-saving) improvement, but again not vice versa." See Chang, p. 920.

[13] Compare with Chang's equation (51), p. 921: $\beta_j=\theta_{Kj}\gamma_j^0+\theta_{Lj}\alpha_j^0+\theta_{L1}(T_{L1}-T_{Lj})$.

where σ_D is the elasticity of substitution between demanders. Solow neutrality in each sector ($\bar{\gamma}_1=\bar{\gamma}_2=0$) implies aggregate Solow neutrality ($e_L|_{\hat{w}=0}=0$) if, and only if, one of the following conditions exists:[14] the elasticity of substitution on the part of demanders equals unity ($\sigma_D=1$) or the Solow rates of technical progress between sectors are equal ($T_{K2}=T_{K1}$).[15] This result parallels Ronald W. Jones' (1966) conclusion that Harrod (Hicks) neutrality in each sector implies aggregate neutrality in the Harrodian (Hicksian) sense if either one of the following conditions exists: the elasticity of substitution on the part of demanders equals unity or the Harrodian (Hicksian) rates of technical progress between sectors are equal.[16]

If sectoral factor proportions differ, then equal Solow, Hicksian, and Harrodian rates of technical progress between sectors cannot all occur. Hence, in the case of unequal sectoral factor proportions, all three classifications of neutrality coexist at both the sectoral and aggregate levels if, and only if, (i) the elasticity of factor substitution in each sector is unitary and (ii) the elasticity of substitution between demanders is unitary.

[14] We ignore the trivial case of equal factor proportions where $(\lambda_{L2}\theta_1-\lambda_{L1}\theta_2)=0$.

[15] According to Chang, "... aggregate Solow neutrality follows if, and only if, either (i) the Solow rate of technical advance, T_{Kj}, is the same in each sector, or (ii) σ_D is greater than unity ..." (p. 922).

[16] Although Jones does not state it, the above conditions are also necessary conditions provided that sectoral factor proportions differ.

International Trade and the Forward Exchange Market

By WILFRED ETHIER*

The forward exchange market has recently been the object of much theoretical interest, mostly centered upon the roles played by interest arbitragers and "pure" speculators. Within this framework, discussions of commercial activity assume that all orders are covered completely, so that the forward rate becomes the relevant exchange rate. But an understanding of the interrelationships between trade and forward exchange ought to be a principal objective of studying the forward market. For example, one of the main issues in the question of fixed versus flexible exchange rates concerns the effects of exchange uncertainty on trade. And the rôle of the forward market, both absolutely and comparatively under the two systems, is quite central here. The objective of this paper, then, is to examine the effect of forward exchange on international trade and the relationship between the market for goods and the forward exchange markets.

The present paper differs from most of the recent literature in that the behavior of merchants involves simultaneously both commercial covering and speculation linked in an essential way. Thus there is no deliberate attempt to divide fictitiously the agents into pure speculators, traders, and arbitragers (although one of my objectives is to determine under what circumstances such a division is valid). In this respect my work resembles that of Peter Kenen, to which it is in a sense complementary.[1] Whereas Kenen shows how firms naturally perform the roles of interest arbitragers and speculators in the course of financing their credit operations, I shall focus on the decisions the firm must make at the time of ordering, regarding both the volume of goods to be imported and the amount of forward exchange cover to obtain, and shall ignore completely the way in which the firm actually finances these imports when payment later falls due. I am thus not directly concerned with the familiar leads and lags of commercial payments.

I. The Behavior of the Firm

Opponents of flexible exchange rates typically assert that exchange uncertainty would have a harmful inhibiting effect on world trade. Forward markets, they claim, would not neutralize this because (a) only comparatively few currencies have well-developed forward markets across a wide spectrum of maturities, and (b) even a well-developed forward market cannot eliminate all risk since ". . . changes in the exchange value of currencies are liable to affect merchants in two different ways—through bringing about a change in the amount payable or receivable in terms of their own currency and through bringing about changes in the prices of the goods exported or imported in terms of their own currency" (Paul Einzig, pp. 53–54). Some also claim that (c) forward cover often involves substantial extra cost, or a "risk premium." In this paper I shall ignore completely the first problem and assume that the firm always has recourse to a well-developed forward market for the relevant date.

Consider now the situation of a typical importing firm. Since I wish to examine the implications of exchange uncertainty, I shall assume that the firm possesses certain knowledge about all other facets of its operations. The firm must decide now on the volume M of imports and on the amount of forward cover, supposing that the price of the imports is denominated in foreign currency, and that both the goods will arrive and payment

* Assistant professor of economics, University of Pennsylvania. Thanks are due to Arthur Bloomfield and Stephen Ross for helpful discussions. An early version of this paper was presented to the 1971 New Orleans meeting of the Econometric Society.

[1] See, in addition, William Branson, ch. 2. After the present paper was completed I became aware of the manuscript by Peter Clark which examines some closely related questions from a somewhat different point of view.

will fall due in, say, ninety days.[2] If α denotes the proportion of the import bill for which cover is obtained, the cost in terms of domestic currency for the goods ninety days hence will be $MQ[\alpha R_F+(1-\alpha)R]$ where Q denotes the foreign price of imports (known when the contract is made), R_F the present forward exchange rate, and R the value of the spot rate relevant when payment falls due. The cost in domestic currency of value-added by the firm will be denoted by $V(M)$, and I shall suppose that the firm faces increasing marginal costs, that is, both V' and V'' are positive. I shall assume $V(M)$ is known to the firm at the time it orders, and so independent of any exchange risk. If P denotes the average price in domestic currency which the firm receives for its product, its profit will be given by

$$(1)\quad \pi(M,\alpha) = PM - V(M) - MQ[\alpha R_F + (1-\alpha)R]$$

The firm is free to decide on M and α, and it wishes to make π as large as possible.[3]

The firm is subject to exchange uncertainty both through the domestic cost of its imports (if $\alpha\neq 1$), and through the size of P. The actual way in which P depends upon the exchange rate will be determined by many factors: the market structure in which the firm operates; the policies of its competitors; the sensitivity of demand for its product to the exchange rate; the length of time between orders; the extent to which consumers anticipate price changes; etc. At one extreme, if the firm were in a situation where all competitors ordered at the same time for the same horizon and if demand were insensitive to the exchange rate, P would be determined simply by the aggregate level of industry imports, independently of the behavior of the exchange rate after the goods are ordered. On the other hand it is not difficult to show that in a competitive market where price, marginal cost, and average cost are equal, P will move *pari passu* with R when given time to adjust (which could be very little if customers with perfect foresight quickly react). I shall express the dependence of P on the exchange rate by the hypothesis

$$(2)\quad P = P^0 + \gamma(R - \bar{R})Q$$

where P^0 is a constant, $1\geq\gamma\geq 0$, and $\bar{R}$ denotes the expected value of the random variable R. Three points should be made about this formulation. First there is no reason to restrict attention to competitive firms, so that P (and Q for that matter) might reasonably be considered to be influenced by M as well as by the exchange rate. I have not added this complication since it seems unlikely to yield very much, especially as V already depends on M in a nonlinear fashion. Second, one would expect P to be sensitive not only to the spot rate when payment is due, but to the behavior of the exchange rate from the time the order is first placed until the last unit has been sold. Thus an optimal strategy could involve dealing simultaneously in a spectrum of forward maturities. I have instead adopted the form in (2) because of its simplicity and because it also seems closer to how firms actually behave. A third assumption implicit in (2) is, however, less compelling. By taking γ as a constant known to the firm I am in effect abstracting a situation where firms' uncertainty about exchange rates dominates their uncertainty as to how a change in the exchange rate would affect them. This assumption glosses over an essential aspect of the problem and will therefore be dropped in the next section, but I shall make it now because it does seem reasonable for at least some cases, it leads to particularly simple results, it better enables me to link my results with the standard literature, and it will turn out to be a convenient basis on which to dichotomize the conclusions of this paper.

The firm then will choose M and α in such

[2] If a domestic futures market happens to exist for its product, the firm must also decide on its sales of futures. This will be ignored in what follows.

[3] I am following convention in supposing that the firm is interested in profits in terms of domestic currency rather than in terms of some portfolio of currencies, or some noncurrency standard. As pointed out by Kenen, this can be unrealistic. Also I shall follow convention by ignoring past commitments, which can now be taken as given. This problem is, however, discussed by S. C. Tsiang, and see also Kenen, p. 151.

a way as to maximize $EU(P^0M - V(M) - MQ[\alpha R_F + (1-\alpha)R - \gamma(R-\bar{R})])$, where E denotes mathematical expectation and U is a Von Neumann-Morgenstern utility function. I shall suppose that U is increasing and strictly concave, so that the firm is risk averse in the sense that it will always prefer a certain return to a fair gamble yielding the same expected return. Then if F denotes the distribution function of R and if differentiation can be taken under the integral, the first-order conditions for a maximum give:

$$\frac{\partial EU}{\partial M} = [P^0 - V'(M) - Q(\alpha R_F + \gamma\bar{R})]E(U') - (1-\alpha-\gamma)QE(RU') = 0$$

and

$$\frac{\partial EU}{\partial \alpha} = \int_0^\infty QM(R - R_F)U'(\pi)dF = QM[E(RU') - R_F E(U')] = 0$$

Now the second condition implies $E(RU') = R_F E(U')$ which substituted into the first condition yields

$$(3) \quad V'(M) = P^0 - Q[\gamma\bar{R} + (1-\gamma)R_F]$$

The distinctive feature about (3) is that it does not depend upon the utility function U. The amount M^* that the firm will order (that is, the solution of (3)) is entirely independent of the firm's attitude towards risk, which is relevant only to the choice of the amount of forward cover to obtain. (Of course, M^* may possibly depend upon merchants' overall attitudes towards risk in the general equilibrium sense that the aggregate net demand for cover helps to determine R_F.)

It will be convenient to now look at the typical firm's problem from a mean-standard deviation point of view.[4] That is, I suppose now that the firm looks only at the expected value E_π of profits and at σ, their standard deviation. The risk averse firm prefers higher values of E_π and lower values of σ. It follows from (1) that

$$(4) \quad E_\pi = P^0M - V(M) - [(1-\gamma)R_F + \gamma\bar{R}]QM + (1-\alpha-\gamma)(R_F - \bar{R})QM$$

and

$$(5) \quad \sigma = (1-\alpha-\gamma)QM\sigma_R$$

where σ_R denotes the standard deviation of R.[5]

It is apparent from (5) that the firm can set σ equal to zero by covering to the extent $\alpha = 1-\gamma$. Indeed such a policy will always remove all exchange risk entirely for then the effect of an exchange rate variation on the domestic value of the payment due for imports will always be matched by an equal and opposite effect on the proceeds of domestic sales. It is clear from (4) that if the firm sets $\alpha = 1-\gamma$ it will maximize E_π by also setting $M = M^*$. Then setting α below $1-\gamma$ (if $R_F > \bar{R}$) or above $1-\gamma$ (if $R_F < \bar{R}$) will increase both E_π and σ. Indeed they change in a linear fashion, as substitution of (5) into (4) gives

$$(6) \quad E_\pi = P^0M - V(M) - [(1-\gamma)R_F + \gamma\bar{R}]QM + \frac{R_F - \bar{R}}{\sigma_R}\sigma$$

The fact that U does not appear in (3) implies that such a policy is efficient: if a firm has $M \neq M^*$, then it can *assure* itself of a higher profit by setting $M = M^*$ and covering appropriately. The situation is illustrated in Figure 1. Point A corresponds to $M = M^*$ and $\alpha = 1-\gamma$. The curve $\alpha = 0$ gives the combinations of E_π and σ that correspond to various levels of M if $\alpha = 0$; $M = M^*$ at point B. Similar curves could be drawn for other values of α. The straight line through A and B is the envelope of these curves and the graph of (6) and represents all efficient alternatives; $M = M^*$ everywhere on this line and α falls as one goes from A to B, α being negative beyond B. If $R_F = \bar{R}$ the line AB

[4] The more important results of this section follow from (3) and so do not depend on mean-standard deviation analysis. But its use is expositionally convenient and will facilitate comparison with the next section's results, which are not so easily generalized.

[5] Henceforth in this paper I assume $R_F \geq \bar{R}$. The case $R_F \leq \bar{R}$ can be handled symmetrically.

will be horizontal, so that every risk averse trader will assume a riskless position and cover to the extent $\alpha=1-\gamma$; E_π cannot be increased by assuming added risk.

The above "separation theorem" provides a justification for the conventional method of analyzing the behavior of participants in the forward market. The firm can be thought of as decomposed into a "pure trader" who imports M^* and always covers his order (not completely, as is commonly supposed, but to the extent $1-\gamma$; this distinction will turn out to be significant) and a "pure speculator" who accounts for the difference between α and $1-\gamma$. But a slight qualification is necessary. It is apparent from Figure 1 that the firm's behavior could involve $\alpha<0$, that is, forward sales of foreign exchange. Such behavior would be overtly speculative and so could quite well involve greater cost,[6] that is, the relevant forward rate could be lower than R_F, as α is negative. In this case the efficient frontier becomes $ABCD$. Along AB the firm imports M^* whereas beyond C the size of M equals the solution of (3) for that value of R_F relevant when $\alpha<0$. Between B and C the roles of the volume of imports and amount of cover specified in the separation theorem are precisely reversed: $\alpha=0$ always but the level of M depends upon the firm's attitude towards risk, that is, the level of imports rather than the degree of forward cover furnishes the vehicle for speculation.

Let M' denote the solution of $V'(M)=P^0-\bar{R}Q$. I shall call M' the efficient level of imports since, as is clear from (3), $M^*=M'$ if the forward rate accurately reflects expectations about the future spot rate, that is, if $R_F=\bar{R}$. The possible divergence of the forward rate from the expected future value of the spot rate, as well as from interest parity, is a prominent feature of the modern theory of forward exchange as developed by John Spraos, Sho Chieh Tsiang, Egon

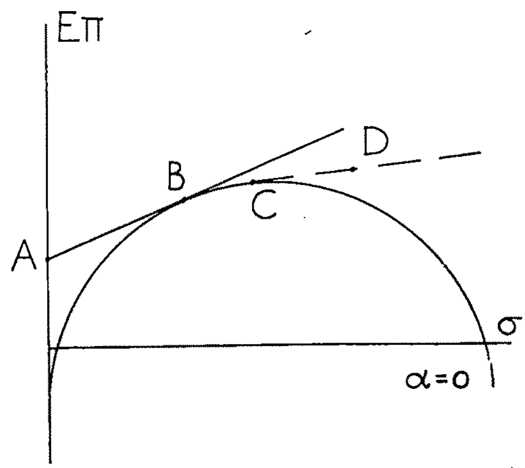

FIGURE 1

Sohmen, and others (see Herbert Grubel for a convenient treatment), and is important for a number of results (see Kenen for example). Merchants frequently ask their bankers whether forward cover currently seems advisable, and in general behave as though they do not take the current forward rate as the best estimate of the future spot rate. Many would argue that market forces would more likely cause R_F and $\bar{R}$ to coincide (with each other as well as with interest parity) under a system of freely floating exchange rates than under one featuring an adjustable peg.[7] Be that as it may, this is quite beyond the scope of the present paper, which will be confined to the implications of the relation between R_F and $\bar{R}$.

Differentiation of (3) leads to

$$(7)\quad \frac{dM^*}{dR_F}=\left(\frac{\partial P^0}{\partial R_F}-(1-\gamma)Q\right)\Big/ V''(M^*)$$

[6] Einzig emphasizes, pp. 104–06, the reluctance of banks to provide forward facilities for overt speculation, and Grubel reports, p. 102, that New York banks require a 10 percent margin deposit. Depending on the size and circumstances of the firm, R_F may or may not be relevant for forward activities that run counter to the firm's trading pattern.

[7] Very briefly, the argument is that if monetary policies should cause domestic and foreign interest rates to differ, then, under a system of floating rates, arbitrage would cause the exchange rate to steadily appreciate or depreciate at a rate to compensate for the difference, thus causing the expected future spot rate, the interest parity level, and the actual forward rate to coincide. Under a pegged system the threat of central bank intervention could make a steady change in the spot rate seem less likely, thus causing the expected future spot rate to differ from the interest parity level, with the actual forward rate falling somewhere in between the two.

Thus, if $R_F > \overline{R}$, M^* will exceed or fall short of the efficient level of imports depending upon whether $\partial P^0/\partial R_F$ is greater than or less than $(1-\gamma)\, Q$.

Sohmen has argued that a premium on forward exchange should not be regarded as a risk premium because "... traders who have assumed commitments to pay in foreign currencies have to pay more for forward than for spot exchange, but other traders who sell their expected foreign exchange receipts forward receive more in exactly the same proportion. For commercial trade as a whole, forward coverage can consequently not be said to be more expensive than spot transactions" (p. 108). If, as Sohmen assumes, all trade is always fully covered, the forward rate is the only relevant exchange rate and, as everyone faces the same forward rate, it can hardly cause distortions in the pattern of trade. But when complete covering is not the universal practice, any departure of R_F from the expected future value of the spot rate necessarily causes inefficiency. This point can be further brought home by also considering a foreign importer of domestic goods who must pay for them on delivery in domestic currency. The analog of (3) for him is

$$W'(X) = P^* - \left[\gamma^* \frac{1}{\overline{R}} + (1-\gamma^*)\frac{1}{R_F}\right] Q^*$$

where X denotes the volume of exports, Q^* their domestic price, W foreign value-added, and P^* and γ^* the foreign counterparts to P^0 and γ. Then the ratio of the domestic price of imports (before value-added so that the goods are comparable internationally) to the domestic price of exports is $[R_F(1-\gamma)+\overline{R}\gamma]\, Q/Q^*$, and the foreign relative price of the same two goods is $Q/Q^*[(1-\gamma^*)/R_F+\gamma^*/\overline{R}]$. If $R_F \neq \overline{R}$ these two relative prices will be equal only in the extreme case where γ and γ^* stand in a certain unique relationship with each other. The usual comparative cost argument then implies that the volume of international trade is not such as to obtain all possible gains. Although the total volume of commercial activity need not be affected by a divergence between the forward rate and the expected future spot rate, in as much as firms selling foreign exchange are influenced in the reverse sense to firms purchasing foreign exchange, as pointed out by Sohmen, the composition of trade will become less efficient. This is because effective relative prices in the two countries will be driven apart when they are sensitive to both R_F and $\overline{R}$.

It is important to realize that this distortion is due entirely to a divergence between the forward rate and the expected future spot rate. Rapid oscillations of these exchange rates, for example, have no such effect provided that the forward rate always reflects expectations about the future spot rate. Also increased uncertainty about the future behavior of R has no effect. An increase in σ_R, for example, will not influence the volume of physical trade but only the amount of forward cover demanded. But will not an increased demand for cover on the part of merchants affect R_F and thus indirectly influence the volume of trade? This is not likely, because domestic and foreign importers and exporters will all demand more cover so that the result will largely consist of an increased volume of forward exchange contracts at the same exchange rate.

It would be of interest to investigate how the demand for imports and for forward cover respond to changes in risk associated with foreign exchange, as represented by σ_R, and to changes in the forward rate. Now it is clear from (3) that the level of imports M^* will be completely unaffected by changes in σ_R, or in any parameter of the distribution function of R other than $\overline{R}$. From (4) and (5) the slope of the line AB in Figure 1 is equal to $(R_F-\overline{R})/\sigma_R$. Thus, since (4) implies E_π is independent of σ_R when $\alpha=1-\gamma$, changes in σ_R result in a pivot of the line AB about the point A, as long as $R_F \neq \overline{R}$. Any risk averse merchant who does not assume the riskless position $\alpha=1-\gamma$ will necessarily be moved to a higher indifference curve by a decline in σ_R, although the level of imports remains unchanged. What about the demand for forward cover? Since M and Q remain unchanged, the demand for forward cover must change in the same proportion as does α.

From (4) E_π will be unaffected by a change in σ_R if α remains constant. It follows therefore that a decline in σ_R will always result in a decline in the demand for forward cover as long as merchants do not display increasing risk aversion to the extreme extent that an increase in wealth is devoted entirely to reducing risk σ and not at all to increasing E_π.[8]

Most writers have assumed that a rise in R_F will cause a fall in both the demand for imports and the demand for cover, and many results in the literature depend on these assumptions.[9] From (7) it follows that a rise in R_F causes a decline in M^* if, and only if, $\partial P^0/\partial R_F<(1-\gamma)Q$, that is, if, and only if, the rise in R_F does not induce a large enough rise in P to increase the profits of a pure merchant assuming the riskless position $\alpha=1-\gamma$. This is true regardless of the firm's actual covering policy. I leave it to the interested reader to investigate the remaining implications of a change in the forward rate.

II. Uncertainty Regarding the Firm's Position

In the previous section I assumed that the typical firm, although uncertain about the future level of the exchange rate, knew what its own profit would be for any value of that rate. This was admittedly unrealistic for many cases, and indeed evades an important issue in the literature. Einzig, for example, states "Even a conservative merchant is not in a position to safeguard himself fully against the indirect effect of the exchange movements, for the simple reason that he is not in a position to foresee the exact extent of that effect. . . . As a result the hedging operation assumes a semi-speculative character" (p. 56). In this section I assume that γ is itself a random variable, distributed independently of R.

[8] Such extreme exceptions will be ruled out if the mean-standard deviation approach is justified by means of a quadratic utility function.

[9] The negative relation between R_F and imports follows from the conventional assumption that all merchants always cover completely (as well as an implicit independence of P from R), but that between R_F and the demand for cover, as Sohmen points out, p. 86, does not.

It follows from (1) that

$$(8)\quad E_\pi = P^0M - V(M) - [(1-\bar{\gamma})R_F + \bar{\gamma}\bar{R}]QM + (1-\alpha-\bar{\gamma})(R_F-\bar{R})QM$$

where $\bar{\gamma}$ denotes the expected value of γ. Also

$$(9)\quad \sigma = QM[(1-\alpha-\bar{\gamma})^2+\sigma_\gamma^2]^{1/2}\sigma_R$$

where σ_γ^2 denotes the variance of γ.

Substitution of (9) into (8) gives

$$(10)\quad E_\pi = P^0M - V(M) - [(1-\bar{\gamma})R_F + \bar{\gamma}\bar{R}]QM + \frac{(1-\alpha-\bar{\gamma})(R_F-\bar{R})}{[(1-\alpha-\bar{\gamma})^2+\sigma_\gamma^2]^{1/2}\sigma_R}\,\sigma$$

In order to delineate the efficient frontier of choices available to the firm, maximize E_π subject to the constraint that σ be equal to some arbitrary value. After some manipulation the first-order conditions for this problem reduce to

$$(11)\quad V'(M) = P^0 - [(1-\bar{\gamma})R_F + \bar{\gamma}\bar{R}]Q - \frac{(R_F-\bar{R})Q\sigma_\gamma^2}{(1-\alpha-\bar{\gamma})}$$

Now the crucial feature of (11), as contrasted with (3), is that it involves the proportion of cover α as well as the level of imports. The separation theorem of Section I is no longer true; the firm's attitude towards risk will help to determine both M and α. Thus when there is uncertainty as to how the individual firm will be affected by the exchange rate it is no longer possible to fictitiously decompose the firm into a pure trader and a pure speculator.

Equations (8), (9), and (11) give three equations in the four unknowns M, α, σ, and E_π. Their solution in terms of E_π and σ is the efficient frontier. Solving these equations ultimately leads to the derivatives shown in equations (12), (13), and (14). Also differentiation of (12) leads to equation (15) which shows that the efficient frontier is strictly concave.

$$\frac{dE_\pi}{d\sigma} = \frac{(R_F - \overline{R})}{\sigma_R} \, \frac{\left[(1 - \alpha - \bar{\gamma})^2 + \sigma_\gamma^2\right]^{1/2}}{(1 - \alpha - \bar{\gamma})} > 0 \tag{12}$$

$$\frac{dM}{d\sigma} = \frac{(R_F - \overline{R})\sigma_\gamma^2\left[(1 - \alpha - \bar{\gamma})^2 + \sigma_\gamma^2\right]^{1/2}}{(R_F - \overline{R})\sigma_\gamma^2 Q \sigma_R\left[(1 - \alpha - \bar{\gamma})^2 + \sigma_\gamma^2\right] + (1 - \alpha - \bar{\gamma})^3 V'' M} > 0 \tag{13}$$

$$\frac{d\alpha}{d\sigma} = \frac{-(1 - \alpha - \bar{\gamma})^2\left[(1 - \alpha - \bar{\gamma})^2 + \sigma_\gamma^2\right]^{1/2} V''}{(R_F - \overline{R})Q^2\sigma_\gamma^2\sigma_R\left[(1 - \alpha - \bar{\gamma})^2 + \sigma_\gamma^2\right] + (1 - \alpha - \bar{\gamma})^3 MQV''} < 0 \tag{14}$$

$$\frac{d^2E_\pi}{d\sigma^2} = \frac{dE_\pi}{d\sigma} \, \frac{\sigma_\gamma^2}{(1 - \alpha - \bar{\gamma})\left[(1 - \alpha - \bar{\gamma})^2 + \sigma_\gamma^2\right]^{1/2}} \, \frac{d\alpha}{d\sigma} < 0 \tag{15}$$

$$\alpha \frac{dM}{d\sigma} + M \frac{d\alpha}{d\sigma} = \frac{\left((1 - \alpha - \bar{\gamma})^2 + \sigma_\gamma^2\right)^{1/2}\left[\alpha(R_F - \overline{R})\sigma_\gamma^2 Q - M(1 - \alpha - \bar{\gamma})^2 V''\right]}{\sigma_R(R_F - \overline{R})Q^2\sigma_\gamma^2\left[(1 - \alpha - \bar{\gamma})^2 + \sigma_\gamma^2\right] + MV''(1 - \alpha - \bar{\gamma})^3 Q} \tag{16}$$

The efficient frontier is depicted by the solid line through C and D in Figure 2. The dotted line through A and B is a reproduction of Figure 1 and represents the efficient frontier in the deterministic case where γ is a parameter with known value equal to $\bar{\gamma}$.

Equations (13) and (14) reveal that a movement along the efficient frontier from C to D and beyond corresponds to an increasing level of imports M and a decreasing proportion of forward cover α. Thus, there is in a sense a tradeoff between mercantile trade and forward cover, with the more speculative firms both importing more and covering less (proportionally) than the more conservative. Will the more speculative firms demand less forward cover absolutely? From (13) and (14), we may derive equation (16), which has the same sign as the numerator term in brackets. If $R_F > \overline{R}$ this term is necessarily positive when M is near zero (and thus α near $1-\bar{\gamma}$) but is necessarily negative when α becomes small. Thus, moving along the curve in Figure 2 from C to D and beyond would cause the total demand for forward exchange to first rise and then fall; the more speculative firm could have either a larger or smaller demand for forward exchange than the more conservative.

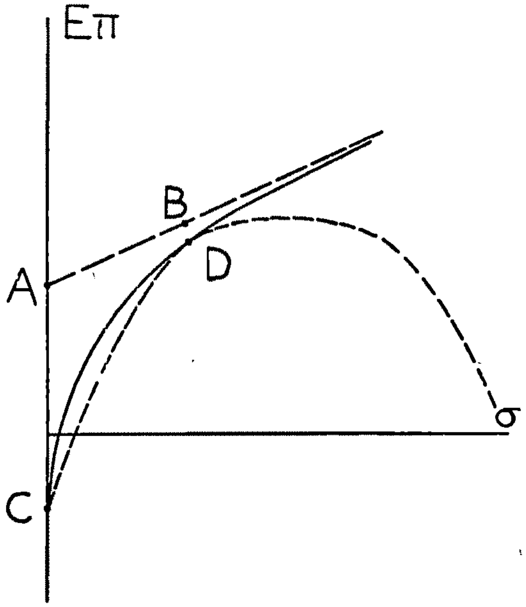

FIGURE 2

Comparison of (11) and (3) reveals that the solution of (11), $M(\alpha)$, is strictly less than M^*, with

$$\lim_{\alpha \to -\infty} M(\alpha) = M^*$$

if (3) reflects the case where γ is assumed to have the value $\bar{\gamma}$ with certainty. Thus, uncertainty about how future profits depend on the future exchange rate must reduce the

level of imports, regardless of the firm's attitude towards risk.[10]

Equation (12) implies that $dE_\pi/d\sigma$ becomes arbitrarily large as α approaches $1-\bar{\gamma}$, and every firm will accept some risk. Indeed the riskless position implies that the firm imports nothing, which entails a certain loss if there are fixed costs. This inability of the merchant to remove all exchange risk is an important distinction between the present treatment and the rest of the literature (including Section I), and is crucial to a consideration of the effects of floating rates on trade.

Comparison of (12) and (8) reveals that the efficient frontier when γ is a random variable is asymptotic, as α becomes small, to the efficient frontier when γ is known with certainty. Thus, if there is serious uncertainty about γ the analysis of Section I gives a good approximation to the behavior of the highly speculative firm, a bad approximation to that of the very conservative firm.

Section I showed that uncertainty about the future exchange rate would reduce the volume of imports by an amount dependent upon the degree to which the forward rate exceeds the expected future spot rate, independently of attitudes toward risk, volatility of the spot rate, etc. Now uncertainty about how the firm's profits depend upon the future spot rate will reduce imports still further, depending upon the willingness of the firm to assume risk. To focus more clearly upon this second factor it is instructive to examine in some detail the situation in the important case where the forward rate accurately reflects expectations about the future value of the spot rate. If $R_F=\bar{R}$ then from (10) it follows that E_π is independent of α, and that E_π will be maximized by ordering M', where $V'(M')=P^0-Q\bar{R}$. Then, from (9), it follows that σ can be minimized for any level of imports by setting $\alpha=1-\bar{\gamma}$. The firm can further reduce risk, at the cost of lower expected profit, by importing less than M'. The resulting efficient frontier is depicted in Figure 3. At point B, $M=M'$ and $\alpha=1-\bar{\gamma}$, while moving from B towards A reduces M, α remaining equal to $1-\bar{\gamma}$.

The situation now is in a sense exactly dual to that of Section I. Every firm will always cover to the extent $\alpha=1-\bar{\gamma}$ whereas the size of its order will reflect its attitude towards risk.

Since M will fall short of M' for conservative firms and will not exceed M' in any case, it is clear that the effect of uncertainty concerning γ will be to reduce the volume of trade. But in contrast to the effect in Section I of a divergence of R_F from $\bar{R}$, this need not be indicative of inefficiency. Uncertainty about γ reflects ignorance of basic economic parameters and should therefore influence the allocation of resources.

Equation (9) implies that $\sigma=QM\sigma_R\sigma_\gamma$ if $R_F=\bar{R}$ and $\alpha=1-\bar{\gamma}$. Thus increasing either σ_γ or σ_R will shift point B horizontally away from the E_π axis, since E_π will not be affected for any given value of M. This will almost certainly reduce the level of imports. (Note also that in this case the effect of such increased uncertainty would be to lower, rather than raise, the forward demand for foreign

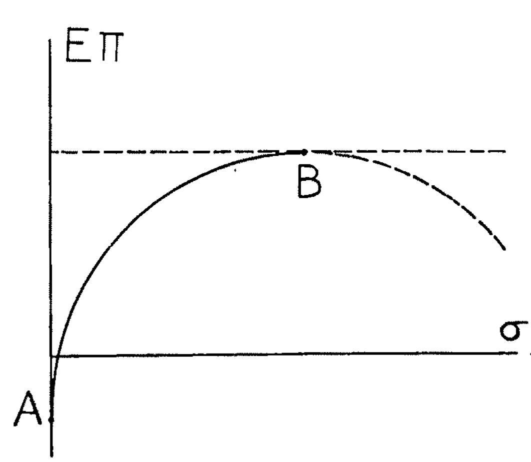

FIGURE 3

[10] Contrast this result with the theory of optimal growth, where uncertainty about the future may either increase or reduce savings, depending upon the response of the degree of risk averseness to changes in wealth. See Leonard Mirman for example. In the case where the expected value of the future spot rate exceeds the current forward rate, movements along the efficient frontier in the direction of higher values of E_π and σ imply that M again increases towards M^* and that α increases beyond $1-\bar{\gamma}$.

exchange.) This analysis could thus be used in an argument against floating rates if one believed that such a system would unjustifiably raise σ_R as a result of destabilizing speculation, etc. Defenders of floating rates, on the other hand, would perhaps assert that such rates would be likely to cause R_F to more closely approximate $\bar{R}$, thus raising efficiency, that σ_R would not likely rise, and that even if it did, the experience of firms under different values of the exchange rate would soon cause a (partially) compensating fall in σ_γ.

This analysis of the firm could be used in a model of the determination of the equilibrium spot and forward rates. If the firm is regarded as typical of the aggregate, the above analysis would give a net demand for forward exchange on the part of trader-speculators as a function of R_F and a net demand for spot exchange determined by past uncovered commitments. The model would be completed by adding a net demand for forward exchange and corresponding supply of spot exchange on the part of interest arbitragers as a function of R_F/R_0 (for given interest rates). There is no point to spelling out such a model in detail here, as it would differ in no essential way from what is already found in the literature (see pp. 97–99 of Sohmen, for example). The equilibrium spot and forward rates simultaneously determined by such a model would turn out to be stable if an increase in the forward rate R_F calls forth an increased net supply of forward foreign exchange. It is worth remarking that the above analysis implies that this condition will almost surely be met near the equilibrium if the equilibrium forward rate closely approximates the expected value of the future spot rate, and if the arbitrage schedule has the conventional shape (see Grubel for example). For an increase of R_F above $\bar{R}$ will almost certainly reduce M and must reduce α below $1-\bar{\gamma}$. But when R_F differs from $\bar{R}$, traders' responses to a change in the forward rate are more ambiguous, as was pointed out in Section I.

III. Concluding Remarks

The foregoing analysis was conducted on the basis of the convention that payment is stipulated in the currency of the exporter. If instead payment were denominated in the importer's currency the basic results would not be affected in any essential way. The exporter would now assume the direct exchange risk whereas the importer would be subject to the indirect exchange risk via the feedback effect on his revenue.

It is possible, however, to also consider the exporter as being subject to a feedback exchange risk. Variations in the exchange rate sometimes affect the cost of production of goods the merchant has contracted to deliver at a stipulated price. For example Einzig claims:

> . . . export trade is not altogether free from the indirect effects of exchange movements, especially in countries whose currencies are susceptible to sufficiently wide fluctuations to react on the internal price level. Thus during the non-stop post-war inflation it was risky for British exporters to sell manufactures for future delivery—even if they covered themselves against the exchange risk by selling forward the currency proceeds—for the simple reason that a devaluation of the pound might cause a sharp rise in the British cost of production in terms of sterling. [p. 54]

But I shall not analyze this situation because it seems to be of much less practical importance than the indirect exchange risk faced by importers and because it also seems unlikely to lead to very different results in any case. Also repercussions of exchange rate variations would cause changes in the production costs of all domestic firms irrespective of whether they were engaged in export trade or not, so it might also be more difficult to construct a model that focused solely on the additional risks faced by a firm engaged in foreign trade.

One might also wish to consider the longer term problem of the effect of exchange risk on the level of investment in firms engaged in foreign trade and on their expected long-run streams of earnings in terms of domestic currency.[11] The present method of analysis can be extended to a formalization of this

[11] See Clark for an interesting investigation along this line.

question without great difficulty, and the basic conclusions do not appear likely to be much affected.

The most important conclusions of this study are as follows. (i) To the extent that firms know how their revenues depend on the future exchange rate, exchange uncertainty influences only the degree of forward cover and not the level of trade. (ii) The pattern of trade will be inefficient to the extent that the forward rate does not accurately reflect merchants' expectations concerning the future behavior of the spot rate. (iii) Uncertainty as to how the firm's revenue depends upon the future exchange rate will cause the level of trade to become sensitive to exchange uncertainty, will reduce the level of trade, and will increase the terms of the tradeoff of expected profit for a reduction in risk. The more speculative the firm, the less significant these factors will be. (iv) If the forward rate accurately reflects merchants' expectations concerning the future spot rate, then firms' attitudes towards risk will be reflected in the level of trade and not at all in the proportion of forward cover. (v) The more closely the forward rate reflects merchants' expectations of the future spot rate the more likely it is that the activities of traders will contribute towards the stability of the spot and forward markets for foreign exchange.

ANNOUNCEMENT

NOTICE TO ALL GRADUATE DEPARTMENTS

The December 1973 issue of the *Review* will carry the seventieth list of doctoral dissertations in political economy in American universities and colleges. The list will specify doctoral degrees conferred during the academic year terminating June 1973. This announcement is an invitation to send us information for the preparation of the list. This announcement supercedes and replaces a letter which was sent annually from the managing editor's office.

The *Review* will publish in its December 1973 issue the names of those who will have been awarded the doctoral degree since June 1972, the titles of their dissertations, and, if possible, a brief (75-word) summary of the dissertation.

By June 30, please send us this information on 3×5 cards, conforming to the style shown below, one card for each individual. Please indicate by a classification number in the right-hand corner the field in which the thesis should be classified. The classification system is that used by the *Journal of Economic Literature* and printed in every issue.

JEL Classification No. ______

Name: LAST NAME IN CAPS: First Name, Initial

Institution Granting Degree: ______

Degree Conferred (Ph.D. or D.B.A.) ______ Year ______

Dissertation Title: ______

Summary

(75-word maximum, or first 75 words will be printed)

Summary may be completed on back of this card or on new card which should be stapled to this.

When degrees in economics are awarded under different names, such as Business Administration, Public Administration, or Industrial Relations, candidates in these fields whose training has been *primarily in economics* should be included.

All items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brown University, Providence, Rhode Island 02912.

NOTES

Nominations for AEA Officers

The Electoral College on March 2 chose R. A. Gordon as nominee for President-Elect of the American Economic Association in the balloting to be held in the autumn of 1973. Other nominees (chosen by the nomination committee) are: for Vice President (two to be elected), Geoffrey H. Moore, Barbara R. Bergmann, Gary S. Becker, and John G. Gurley; for members of the Executive Committee (two to be elected), Andrew Brimmer, Anne P. Carter, Paul M. Sweezy, and Peter A. Diamond.

Under a change in the bylaws as described in the *Papers and Proceedings* of this *Review*, May 1971, page 472, additional candidates may be nominated by petition, delivered to the Secretary by August 1, including signatures and addresses of not less than 6 percent of the membership of the Association for the office of President-Elect and not less than 4 percent for each of the other offices. For the purpose of circulating petitions, address labels will be made available by the Secretary at cost.

A Group Life Insurance plan for members of the American Economic Association and their dependents is available through the Smith-Sternau Organization of New York. Eligible members may be covered up to $50,000 with $10,000 available under age 50 without medical evidence. A descriptive brochure and enrollment materials will be sent to each member by the Plan Administrator of the Smith-Sternau Organization no later than June 30, 1973.

The fourth Congress of the International Economic Association, to be held in Budapest, Hungary, from August 19–24, 1974, will be open to economists of all countries. The local arrangements committee, expecting a record attendance from both Eastern and Western countries, has reserved 2,400 beds. The program committee is composed of twelve members from as many countries. The general theme of the Congress, *Economic Integration: Worldwide, Regional, Sectoral*, will be treated in three plenary sessions on the first two days, in five sessions each of ten separate working groups, and in two concluding plenary sessions devoted to reports on the proceedings of the working groups. The ten working groups will have the following assignments: Measuring the degree or progress of economic integration; Sectoral Integration: agriculture, transport, energy, selected industries; Industrial Policy: location, technology, multinational firms, competition, and integration of product markets; Migration and integration of labor markets; International capital movements and integration of capital markets; Monetary and Fiscal integration; Socio-Political and institutional aspects of integration; Integration of less developed areas and of areas on different levels of development; Integration by market forces and through planning; World Trade and Interregional Trade: trends and structural changes.

A complete set of *The American Economic Review* from September 1939 to date is available as a donation to an organization, small college, or foreign institution. Please contact Mrs. Paul Webbink, 17 Cohawney Road, Scarsdale, New York 10583.

A Seminar-Workshop on Energy, Growth, and Pollution, sponsored by the departments of geology and economics, Ohio University, will be held July 16–18, 1973. For details, contact R. K. Koshal, 315, Copeland Hall, or Workshop Office, 301, Tupper Hall, Ohio University, Athens, Ohio 45701.

The National Economists Club, an 850-member professional economists organization, held its fifth annual meeting at the International Club of Washington on February 28, 1973. They announce the election of the following officers for the coming year: President, Frank W. Schiff, Committee for Economic Development; Vice Presidents, Nancy H. Teeters, The Brookings Institution and Robert R. Nathan, Robert R. Nathan Associates; Secretary, Grace Taylor, Loomis-Sayles & Company; Treasurer, St. Clair J. Tweedie, American Textile Manufacturers Institute.

New Journal

Research on Consumer Behavior: An interdisciplinary journal will be issued quarterly with the first issue scheduled for July 1974. It will contain two sections: Articles and Communication Notes. Its purpose is to publish empirical research on consumer behavior with special emphasis on articles with interdisciplinary content or interest. For information as to the criteria for articles and communication notes as well as for instructions on manuscript format to be used when submitting articles, write for an *RCB* style sheet to: Ronald E. Frank, editor, *Research on Consumer Behavior*, The Wharton School-W-253, University of Pennsylvania, Philadelphia, Pennsylvania 19174.

A New Series of Economic Research Papers

United Kingdom government economists have commenced publication of their own series of economic research papers under the title *Government Economic Service Occasional Papers*. The aim of the series is to summarize research work which has been undertaken by *UK* government economists in the normal course of their official work but which is also likely to be of interest to economists in general. The *Papers* are published by Her Majesty's Stationery Office. Single copies may be purchased or a standing order for the series as issued placed with the official agent of HMSO in the United States: Pendragon House, Inc., 899 Broadway Avenue, Redwood City, California 94063.

The Volunteer Speakers Service encourages American experts from the professional, academic, and artistic communities to meet with their foreign colleagues or to lecture to select audiences while they are traveling abroad. American scholars and specialists are cordially invited to volunteer as a speaker if they are traveling abroad and have sufficient time at any stop to allow for programming there or in nearby countries. A Volunteer Speaker may be asked to deliver lectures at a university or before other selected audiences, to conduct or participate in a seminar or panel discussion, or perhaps to attend a social event offering an opportunity for informal contact and the exchange of ideas with foreign experts in his field of interest. Interested persons should send their travel plans and professional background details to: Overseas Speakers Division, ICS/S—U.S. Information Agency, Washington, D.C. 20547.

The National Association of Business Economists will hold its next annual meeting at the Plaza Hotel in New York City on September 12–14, 1973. Further details can be obtained from the Arrangements Chairman: John J. Casson, Associate Economist, Brown Brothers Harriman & Co., 59 Wall Street, New York, New York 10005.

Each year since 1954 the Council of the Operations Research Society of America has offered the Lanchester Prize for the best English language published contribution in operations research. The prize for 1972 consists of $2,000 and a commemorative medallion.

The screening of books and papers for the 1972 prize will be carried out by a committee consisting of the three most recent past presidents of the Society. Nominations should be sent to Walter E. Cushen, chairman, 1972 Lanchester Prize Committee, 6910 Maple Avenue, Chevy Chase, Maryland 20015.

The department of economics of the University of Wyoming will sponsor the second annual Bugas Summer School Program in Economics during the 1973 Summer Session. The visiting lecturers for the session include: Ronald G. Cummings, University of Rhode Island, who will offer a course in resource economics and Mohamed A. El-Hodiri, University of Kansas, who will offer a course in mathematical economics. The session will be held June 11–August 3, 1973. The Institute on Health Manpower Planning will be held in August. The exact dates and any information may be obtained by writing the Department of Economics, Box 3985, University Station, Laramie, Wyoming 82071.

The Carolina Population Center of the University of North Carolina is planning a postdoctoral Summer Institute in Population, consisting of workshops for sociologists, economists, psychologists, anthropologists, and political scientists who are interested in research and teaching in the population field, but who need to strengthen and broaden their background in this area. The Institute will be held four weeks, beginning July 30, 1973. Individuals selected to participate will be paid a salary, per diem, and travel. It is anticipated that the Center for Population Research, National Institute of Child Health and Human Development, will support the Summer Institute. Please request details from Dr. Vaida Thompson, director, Summer Institute in Population, Carolina Population Center, University of North Carolina, Chapel Hill, North Carolina 27514. Telephone: 919+933-2055.

The Conference Group on Modern Portugal announces a Workshop on Modern Portugal (1820–1973) to be held October 10–14, 1973 at the New England Center of the University of New Hampshire. Sponsored by a grant from the Council for European Studies, the Workshop will provide an opportunity for social science and history graduate students with an interest in Portugal to meet with American and European scholars currently engaged in studies of social change in Portugal. For details, write Dr. Joyce Riegelhaupt, Institute of Latin American Studies, Columbia University, New York, New York 10027.

A program designed to develop new capabilities in population dynamics has been announced by the Interdisciplinary Communications Program of the Smithsonian Institution. This new effort, called the International Program for Population Analysis and funded by the U.S. Agency for International Development, invites members of the social sciences and humanities—particularly those from the "Third World" of less developed countries—to undertake modest studies of contemporary problems directly related to the development of population policies. Further information may be obtained by writing for the trilingual Publication No. TP-100 (English, French, Spanish) that is available from the Interdisciplinary Communications Program, Smithsonian Institution, 1717 Massachusetts Avenue, N.W., Washington, D.C. 20036.

Deaths

Howard Bourne, associate professor, Wayne State University, Dec. 1, 1972.

Ragnar Frisch, Oslo, Norway, Jan. 31, 1973.

Orris C. Herfindahl, senior research associate, Resources for the Future, Dec. 16, 1972.

N. Arnold Tolles, visiting professor of economics, State University of New York, Geneseo, April 10, 1973.

Leland S. Van Scoyoc, professor emeritus, Bowling Green State University, Jan. 7, 1972.

Retirements

Benjamin Rowe, professor emeritus, social science department New York City Community College of the City University of New York, Sept. 1, 1972.

Clarence W. Tow, senior vice president and director of research, Federal Reserve Bank of Kansas City, Oct. 31, 1972.

Visiting Foreign Scholars

Mrinal Datta-Chaudhuri, Indian Statistical Institute, Delhi: visiting professor of economics, University of Minnesota, Mar. 1973–Mar. 1974.

Assaf Razin, Tel-Aviv University: visiting professor of economics, University of Minnesota, spring quarter, 1973.

Promotions

Charles R. Chittle: associate professor of economics, Bowling Green State University.

Rolf Craft: associate professor of economics and business administration, Luther College.

Raymond J. Doll: vice president and director of research, Federal Reserve Bank of Kansas City, Nov. 1, 1972.

Paul F. Hass: associate professor of economics, Bowling Green State University.

Roger M. Kubarych: special assistant, foreign department, Federal Reserve Bank of New York.

Stanton C. Lindquist: associate professor of economics and business administration, Luther College.

Glenn H. Miller, Jr.: vice president and senior econonist, Federal Reserve Bank of Kansas City, Jan. 2, 1973.

J. David Reed: associate professor of economics, Bowling Green State University.

Sheldon W. Stahl: vice president and senior economist, Federal Reserve Bank of Kansas City, Jan. 2, 1973.

Donald L. Sternitzke: professor of economics, Bowling Green State University.

Frank Zahn: associate professor of economics, Bowling Green State University

Administrative Appointments

Fred Abel, U.S. Department of Agriculture: chief, Economic Analysis Branch, Implementation Research Division, Environmental Protection Agency, Dec. 1971.

Dane J. Cox: treasurer, Colby College, Jan. 30, 1973.

Robert Dockson: chief executive officer, California Federal Savings and Loan Assn., Jan. 17, 1973.

L. Aubrey Drewry, Western Carolina University: dean, College of Business and Applied Science, Marshall University, July 1, 1973.

Paul Gerhardt, National Air Pollution Control Agency: chief, Standards Research Branch, Implementation Research Division, Environmental Protection Agency, Sept. 1971.

Herbert G. Geyer: chairman, department of economics, Hunter College, City University of New York, July 1, 1972.

Molly K. S. C. Lee: chairman, department of social sciences and dean, division of humanities, New York Institute of Technology, Sept. 1, 1972.

F. K. Levy, Rice University: dean, College of Industrial Management, Georgia Institute of Technology, 1972–73.

Geoffrey H. Moore: vice president-research, National Bureau of Economic Research, Feb. 1, 1973.

Robert W. Pullen: administrative vice president, Colby College, Jan. 30, 1973.

H. Leslie Robinson: chairman, department of economics and business administration, Elbert Covell College, University of the Pacific, Dec. 20, 1972.

Marquis Seidel, Back and Sterling, Inc.: chief, Systems Evaluation Branch, Implementation Research Division, Environmental Protection Agency, Apr. 1972.

Gloria M. Shatto, University of Houston: associate dean, College of Industrial Management, Georgia Institute of Technology, 1972–73.

Richard D. Teach: associate dean, College of Industrial Management, Georgia Institute of Technology, 1972–73.

Appointments

John Adams: instructor in economics and business administration, Luther College.

Fred C. Allvine, Northwestern University: associate professor of industrial management, Georgia Institute of Technology, 1972–73.

Scott Atkinson, University of Colorado: economist, Implementation Research Division, Environmental Protection Agency, Aug. 1972.

Uri Ben-Zion, University of Chicago: visiting professor of economics, University of Minnesota, Sept. 1972–June 1973.

Brian Bock: instructor in economics, Luther College.

Patricia Brenner: assistant professor, department of economics, Williams College, Sept. 1972.

John Ciccolo: economist, Money and Finance Division, Federal Reserve Bank of New York.

James F. Courtney: instructor of industrial management, Georgia Institute of Technology, 1972–73.

David A. Couts: coordinator of research, Motor Vehicle Manufacturers Assn., Detroit.

John Danforth, Northwestern University: assistant professor of economics, University of Minnesota, Sept. 1972.

Mark Z. Fabrycy, New York University: professor of economics, Wright State University, Jan. 1973.

Elon Gilbert: visiting scholar, Food Research Institute, Stanford University.

James R. Hibbs, U.S. Department of Commerce: assistant to director, Implementation Research Division, Environmental Protection Agency, Dec. 1972.

W. Whitney Hicks: visiting associate professor, Food Research Institute, Stanford University.

John H. Hoag: assistant professor of economics, Bowling Green University.

Martin E. Horning: instructor of economics, Bowling Green University.

Robert J. Jones, Columbia University: instructor in economics, Skidmore College, Feb. 1973.

Jay H. Levin, Federal Reserve Board: associate professor of economics, Wayne State University, Jan. 1, 1973.

Wuu-Long Lin: research associate, Food Research Institute, Stanford University.

John McCracken: economist, Foreign Research Division, Federal Reserve Bank of New York.

Edward F. McKelvey: assistant professor, department of economics, Williams College, Sept. 1972.

Bridger M. Mitchell, Department of Health, Education, and Welfare: staff member, economics department, The Rand Corporation, Nov. 1972.

Marcelo Peinado, Utah State University: associate professor of agricultural economics, Elbert Covell College, University of the Pacific, Aug. 16, 1972.

Henry M. Peskin: research associate, National Bureau of Economics Research, Dec. 1972–Dec. 1973.

James L. Plummer, U.S. Embassy, Bogota, Colombia: economist, Environmental Protection Agency, Implementation Research Division, July 1972.

Robert Reck, University of Maryland: economist, Implementation Research Division, Environmental Protection Agency, Dec. 1971.

Marshall Rose, Xerox Corporation: economist, Implementation Research Division, Environmental Protection Agency, June 1972.

David K. Sandberg: economist, Balance of Payments Division, Federal Reserve Bank of New York.

Richard A. Sandell: associate professor of international business and economics, Elbert Covell College, University of the Pacific, Aug. 16, 1972.

Peter G. Sassone: assistant professor of economics, Georgia Institute of Technology, 1972–73.

Rudolph K. Schnabel: instructor, department of economics, Iowa State University.

Paul T. Schultz, The Rand Corporation: professor of economics, University of Minnesota, Sept. 1972.

David L. Scott: assistant professor of economics, Florida Southern College, Sept. 1972.

Robert J. Shiller, Massachusetts Institute of Technology: assistant professor of economics, University of Minnesota, Sept. 1972.

William L. Stringer: assistant professor of economics, Bowling Green State University.

Dennis Tihansky, The Rand Corporation: operations research analyst, Implementation Research Division, Environmental Protection Agency, Jan. 1972.

Henry C. Wallich: senior research associate, National Bureau of Economic Research.

William Watson, Washington State University: economist, Implementation Research Divisi mental Protection Agency, June 1972.

Leaves for Special Appointn

Garry M. Crane, National Bureau of Sta ing economist, Department of Supply Canada, Sept. 1972.

Paul B. Downing, University of Californ economist, Implementation Research Di ronmental Protection Agency, July 1972–

B. F. Kiker, University of South Car professor, University of Edinburgh, Scotl 1973.

George von Furstenberg, Indiana Unive professor of economics, University of Au many, fall semester 1972.

Gary M Walton, Indiana University: v sor of economics, University of Hawaii, sp 1973.

Resignations

Irving Auerbach, Federal Reserve Bank Aubrey G. Lanston & Co., Inc.

John Buttrick, University of Minnesot versity, June 1973.

Peter Gregory, University of Minnesot of New Mexico, June 1973.

Ralph Hofmeister, University of Mi World Bank June 1972.

David T. Lapkin, University of No Chapel Hill, Dec. 31, 1972.

Richard G. Marcis, Bowling Green Stat Federal National Mortgage Assn., July 19

Allan P. Rahn, Iowa State University: Georgia.

David E Vanderford, Federal Reserve York: Townsend & Greenspan, Inc.

NOTE TO DEPARTMENTAL SECRETARIES AND EXECUTIVE OFFICERS

When sending information to the *Review* for inclusion in the Notes Section, please use the following

A. Please use the following categories:

1—Deaths
2—Retirements
3—Foreign Scholars (visiting the USA or Canada)
4—Promotions
5—Administrative Appointments
6—New Appointments
7—Leaves for Special Appointments (NOT
8—Resignations
9—Miscellaneous

B. Please give the name of the individual (SMITH, John W.), his present place of employment or er new title (if any), and the date at which the change will occur.

C. Type each item on a separate 3×5 card and please do not send public relations releases.

D. The closing dates for each issue are as follows: *March*, November 1; *June*, February 1; *Septer December*, August 1.

This announcement supersedes and replaces a letter which was sent annually from the managing editc items and information should be sent to the Assistant Editor, *American Economic Review*, Box Q, Brow Providence, Rhode Island 02912.

The American Economic Review

ARTICLES

SEPTEMBER 1973

THE AMERICAN ECONOMIC ASSOCIATION

Founded in 1885

• Published at George Banta Co., Inc., Menasha, Wisconsin.

• THE AMERICAN ECONOMIC REVIEW, including four quarterly numbers, the *Proceedings* of the annual meetings, and *Directory* and Supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September, and December.

• Membership dues of the Association are $21.00 a year, which includes a year's subscription to both the *American Economic Review* and the *Journal of Economic Literature*. A three year junior membership of $10.50 per year is available to registered students. Subscriptions by nonmembers are $31.50 a year, and only subscriptions to both publications will be accepted. Single copies of the *Review* and *Journal* are $4.50 each. Each order for copies of either publication must also include a $.50 per order service charge. Orders should be sent to the Secretary's office, Nashville, Tennessee.

• Correspondence relating to the *Papers and Proceedings*, the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address may be sent to the secretary, Rendigs Fels, 1313 21st Avenue, South, Nashville, Tennessee 37212. To be effective, notice of change of address must reach the secretary by the 1st of the month previous to the month of publication. The Association's publications are mailed by second class and are not forwardable by the Post Office.

• Second-class postage paid at Nashville, Tennessee and at additional mailing offices. Printed in U.S.A.

R. G. Gordon

R. A. GORDON

Distinguished Fellow
1972

In honoring Robert Aaron Gordon, we applaud craftsmanship in the service of compassion. From his early books *Business Leadership in the Large Corporation* and *Business Fluctuations* to his recent work on the structure of labor markets, culminating in *The Goal of Full Employment*, he has steadfastly pursued two objectives for economics: that it should fit the facts of modern economic life, and that it should find ways to improve the human condition. In a time when it was not fashionable, he has been the practical man's theorist, the theorist's practical man, and everybody's enemy of stereotypes. His contributions to economics include his institutional work on the control of large corporations, his theoretical and empirical analysis of business cycles, and his close study of manpower problems. For all of this, we thank him.

The 1973 Report of the President's Council of Economic Advisers: The Economic Role of Women

By Barbara R. Bergmann and Irma Adelman*

The 1973 Economic Report of the President devotes an entire chapter (ch. 4) to the economic role of women in the United States. In this chapter, the Report recognizes that economic discrimination against women exists and, by the length and thoroughness of the analysis describing its dimensions and consequences, implies that such discrimination constitutes a serious economic (and social) problem. The Report does not attempt to minimize the extent to which job segregation, earnings differentials, higher unemployment rates exist, and the lack of improvement in each component over the last few decades.

As economists, we are particularly pleased to have the official imprimatur of an Economic Report on the view that discrimination does indeed exist. Some economists have the tendency to minimize the importance of nonpecuniary forces in influencing decisions made within the firm, and have been reluctant to admit the possibility of discrimination unrelated to real or perceived productivity differences. We believe that a proper analysis of discrimination is yet to come; such an analysis will have to fuse elements of economics, sociology, psychology, and history. Employers *do* refuse to hire women for certain occupations. Instead they hire men exclusively and pay them more than they would have to pay women of equal ability. The court records are now full of such cases,[1] but such data will never be explained on the basis of a model which includes in the objective function of the employer only monetary profits. Nor can models which assume that employers' decisions about hiring are based on inborn, unchanging, unexplained "tastes" do justice to the social forces, both internal and external to the firm, which bear on such decisions.

Specifically, it is well known that the average woman college graduate who works full time all year ends up with about the same income as the average male high school dropout. The gross earnings differential works out to be between 35 and 57 percent, depending on the data base used to make the calculation. The Report puts the differential due to discrimination at about 20 percent, but this seems low. In a recent article, Isabel Sawhill reviewed seven econometric studies of male-female earnings patterns. In six of them,[2] the differences which could be attributed to discrimination were above 29 percent and ranged up to 43 percent. The seventh study[3] estimated the difference which might be attributable to discrimination as 12 percent, but arrived at this figure by classifying as nondiscriminatory the differences in the distribution of men and women among detailed occupations. Since

* Professors of economics, University of Maryland. We would like to thank Carolyn Shaw Bell, Nancy Gordon, June O'Neill, Isabel V. Sawhill, and Phyllis Wallace for helpful comments on a previous draft.

TABLE 1—EMPLOYMENT BY SEX IN OCCUPATIONS CLASSIFIED BY EXTENT OF WOMEN'S REPRESENTATION IN 1960
(thousands)

Occupations in which women were (in 1960)	1960			1970		
	Women	Men	Total	Women	Men	Total
Underrepresented (0–25%)	2,110	31,231	33,341	3,315	32,436	35,751
Well represented (25–45%)	3,503	6,332	9,835	4,470	7,546	12,016
Overrepresented (45–100%)	15,394	5,863	21,257	20,670	6,930	27,600
Total	21,007	43,426	64,433	28,455	46,912	75,367

employers will typically restrict certain jobs to men and since this restriction is a principal mode of discrimination, a major part of the difference in occupational distribution must be classed as due to discrimination. The fact that women in the past have not trained for or applied for such jobs has been due more to women's realism about the prospects for payoff of such training or applications than to women's voluntary embrace of a benign "role differentiation."

The Report places a great deal of emphasis on the fact that women of a given age have up to now averaged less work experience than men of that age. This emphasis on work experience would be justified if experience for women meant the same as experience for men, but, unfortunately, it does not. Women typically are relegated to jobs in which experience adds little to productivity. Consider the newly hired junior executive and his newly hired secretary. They both may have gone to the same college, got the same grades, and even have majored in the same subject. But, for him, experience will mean learning, increased responsibilities, increased contacts, increased self-realization. In her case, it is likely that the development of work skills will have ceased in six months. The Report documents a strong trend towards increase in labor market attachment in women of child-bearing age; this trend will do little good in decreasing the earnings gap unless occupations are desegregated.

The difference in earning power between men and women is an important contributor to the incidence of poverty and welfare dependency in this country. In 1971, 40 percent of families "with female head" were classified as poor as compared to 7 percent of families "with male heads."[4,5] The wages offered to working women (particularly Black women) frequently provide incomes close to or below the amounts welfare mothers get out of welfare.

With respect to job segregation, the Report indicates (on the basis of an analysis of the proportion of women in 197 occupations) that women tend to be concentrated in "women's occupations," and that there has been only a very small change in the direction of less segregation between 1960 and 1970. We have retabulated the 1960 and 1970 Census data by occupation given in the Report in a way which shows quite graphically the continued occupa-

[4] Some of the families with male head are entirely supported by women, so the difference between 40 and 7 percent understates the effect of low earnings for women on poverty incidence.

[5] The quotation marks in this sentence convey our disagreement with the Census Bureau's use of the term "head." Census cannot mean by it "highest paid worker" since any family including a husband is classed as being "male headed" regardless of his earnings. They must mean "family boss."

tional segregation of women (Table 1). In 1960, 73.3 percent of the women workers were in those occupations in which (in 1960) women were grossly overrepresented; in 1970 the proportion was 72.6 percent. The Report's index of occupational segregation, computed somewhat differently, also changed very little. However, this fixity of the degree of segregation meant a deterioration in the position of women, since in 1970 women constituted a greater proportion of the labor force. In 1960, the women in occupations in which women were overrepresented made up 23.9 percent of the labor force. By 1970, the share of women in these occupations to the total labor force had advanced to 27.4 percent. These occupations were already relatively overcrowded in 1960, and as a result, productivity (and wages) were relatively low.[6] This increase in the relative size of these occupations probably increased the amount of overcrowding and further increased the gap between productivity in "men's" and "women's" occupations. This is corroborated by the decrease between 1956 and 1969 in the ratio of female to male earnings (from 63 percent to 59 percent), a large part of which is due to a relative decline in wages of female clerical workers.

The Report documents the fact that women have generally higher unemployment rates than men and that this differential has been more pronounced in recent years. It ties the worsening trend to the relatively large increase in the labor force participation of women. We agree that the increase in labor force participation rate for women is a part of the cause but not for the reason given in the Report. There emphasis is placed on the fact that a person entering the labor force necessarily has a spell of unemployment while looking for a job. While this is true, the length of such spells and thus the unemployment rate is influenced by the number of job slots for which women are considered eligible as compared with the number of women in the labor force. In our view, the unemployment problem of women has worsened relative to the unemployment problem of men for the same reason wage differentials have increased: because of the segregation of women into "women's" occupations which have become relatively more overcrowded due to the relative increase in the female labor force.

The Report also indicates that quit rates and layoff rates are higher for women than for men. The issue of high turnover among workers is one in which cause and effect are hard to disentangle. The common view is that women have high turnover and enter and leave the labor force more frequently than men because of "their (sic) home responsibilities." In fact, of course, women are consigned for the most part to jobs that have very little interest, opportunity, or pay. Typically, women's jobs are also those for which there is no penalty for high turnover; whether one stays or whether one quits and gets another such job immediately or after an interval, the results in terms of pay and advancement remain much the same. Men who happen to be in this kind of job also have high turnover. Women's relatively high quit rates (2.6 percent per month as opposed to 2.2 percent for men, uncorrected for occupational differences) are seen by some as justifying the exclusion of women from good jobs and by others as an effect of their exclusion. Some may argue that women will have to get over their "lesser attachment to the labor force" before better jobs will open to them, and others may argue that employers will have

[6] The number of men in occupations where women are overrepresented increased also. This is not inconsistent with the view that these occupations are overcrowded. An occupation which a college graduate woman cannot leave because of limited opportunities elsewhere may look relatively good to a male high school dropout.

to open better jobs to women before such improvements in women's turnover can be expected. In fact, these two things will have to occur simultaneously.

The Report gives currency to the recently prominent view that a high turnover rate among women is important in explaining their higher unemployment rates. This view derives, in our opinion, from a misinterpretation of the undoubted fact that all unemployed persons have a history of being separated from a job or entering the labor force. Both turnover *and* the balance of supply and demand for a group's services affect its unemployment rate, but the latter factor is likely to be of far greater importance than the former.[7]

There are, in the Report, a number of instances which we feel reflect a great deal of sociological conservatism. The treatment of paid work outside the home is an example:

> Women work outside the home for the same reason as men. The basic reason is to get the income that can be earned by working. Whether—for either men or women—work is done out of necessity or by choice is a question of definition. If working out of necessity means working in order to sustain biologically necessary conditions, probably a small proportion of all the hours of work done in the United States, by men or women, is necessary. If working out of necessity means working in order to obtain a standard of living which is felt by the worker to be desirable, probably almost all of the work done by both men and women is necessary. [p. 89]

This passage, while clearly reflecting liberal intentions, misses some very important reasons why women (and men) work. They work not only to contribute to the family's funding for goods and services, but for greater personal autonomy in spending, for status inside and outside the family, to occupy themselves in an interesting way, to meet people, to have the excitement of being in a contest for advancement, to reduce the amount of housework they do, and to get away from spending all day with their children. The jobs most women now have tend to fulfill these desires to a less satisfactory extent than the jobs men now have, but they frequently fulfill them better than staying home would.

A woman's work also reduces her own financial uncertainty. A working woman whose husband dies or whose marriage breaks up is in a far better economic position than a similarly bereft housewife in terms of experience, entree, contacts, work habits, and asset ownership. In this day of unstable marriages, a woman who refrains from working during marriage is taking a risky position with her own financial future and that of her children. One year after divorce only 38 percent of ex-husbands are in full compliance with court-ordered child support payments. After five years, the figure drops to 19 percent.[8]

One of the reasons given in the Report for women's greater unemployment, turnover, and lower wages is that, "A wife seldom is free to migrate to wherever her own prospects are best" (p. 99). This statement represents prejudicial past practice and is not necessarily the way things will be in the future. Although casual empiricism is our only source of data on this, it seems to us that the practice of considering only the man's career is far less prevalent than it used to be. The economic problem of couples with specialized job requirements is not really going to be an easy one to solve. One possibility for professional people is geographic mobility early in life, with a postponement of marriage until the person has settled into the slot he or she is

[7] See Bergmann for a more extended discussion of this issue.

[8] See K. Eckhard.

willing to occupy from then on. A second is lessened mobility throughout life, which could not necessarily be to the detriment of the quality of life in this country. A third is the removal of institutional barriers to joint employment. A fourth is the couple's agreement to move to a location where the partner who is weakest in the labor market has the best chance.

Along a similar vein, the Report assumes that when women have children there is no alternative but to drop out of the labor force for a number of months or years. The present authors themselves are exceptions to this "rule." Speaking of those higher income women who do drop out, the Report notes "a considerable sacrifice of earnings" and infers "that these women have therefore placed a very high value on the personal attention they can give their children" (p. 107). Here again we would argue that it is unfruitful to analyze decisions concerning child rearing as being based on unchanging internalized tastes. The appearance of Betty Friedan's book seems to have lowered by quite a lot the "value on the personal attention (women) can give their children." Some women now believe that a lower quantity of personal attention measured in terms of time may increase the quality of that attention to the gain of both children and their parents.

One outstanding omission in the Report is any discussion of changes in the distribution of household tasks between husband and wife, an issue which surely goes to the heart of the women's liberation movement.

The Report asserts there is no practical way to assign a market value to the unpaid work performed at home, subject it to income tax, and thus to tax it comparably with other income and so remove the bias in favor of unpaid work at home. This is quite untrue. The new deduction for paid child care is precisely a move to treat paid and unpaid work similarly. (If domestic work is performed by a family member on an unpaid basis, the value of the service is automatically "deductible," since it is not reported as income.) A deduction for salaries for all paid domestic work by non-family members would seem to be the logical extension. If it is argued that this would favor the rich, then the deduction could be reduced for higher income groups and/or a maximum put on the size of the deduction, and further might be made contingent on all family adults being in the labor force or at school.

In discussing policy with respect to employment discrimination, the Report mentions the many Titles, Acts, and Executive Orders which mandate an end to unfair employment, promotion, and pay practices. It fails to mention that enforcement efforts have been almost nil, despite the fact that very few if any firms, universities, or even government offices are in compliance. What enforcement efforts have been made have raised up loud cries of reverse discrimination.

The present authors are firmly opposed to reverse discrimination and believe it unnecessary and undesirable. Given a fair shake, there is no doubt in our minds that women can make it to full equality with men in the job market. The problem, as we see it, is one of how to implement the transition to "sex-blind" hiring practices, in the presence of prevalent conscious and subconscious discrimination and role casting (on both sides of the "hiring hall"). In this context, there is much to be said for sensibly administered hiring goals of a statistical nature in preference to mere employer statements of good intentions. Naturally, we do not mean a 50 percent ratio across the board. If, for example, women constitute 35 percent of those who by objective criteria qualify for a given rung of an occupation, they should have approximately 35 percent of those jobs, especially in large firms whose very size makes it possible to assume that depar-

tures from the average cannot be explained on purely statistical grounds.

To summarize, the chapter of the President's Economic Report on the economic rôle of women is a creditable coverage of the data, of the problems, and of the issues. It touches almost all the bases one would expect. What would have been welcome and what is missing is a rather more open view of what the problem is, and what the future possibilities are for changing the economic and social role of women. While painting an accurate, reasonably bleak picture of existing reality, the Report tends to underestimate the possibilities and need for social change, and to underemphasize the role of noneconomic forces in having brought about the current situation. Almost absentmindedly, it ignores the transformations in social relations and attitudes, and in economic practices which seem to be occurring and which must accelerate if significant change is to occur. Unfortunately also, the Report suggests very little by way of positive programs.

We must also point out that, however much we are pleased about the attention given to women's problems in the President's Economic Report, we deplore the fact that the Council has apparently reduced its concern in the social area more generally. The issue of unemployment, which by legislative history should be the Council's major concern, is given explicit attention in two passages which together occupy about two pages in the Report. One sentence is as much as we could find devoted to the economic problems of Blacks. Poverty has disappeared as a subject of the President's economists' concern. We can only hope that next year's Report will show that this omission is temporary.

The 1973 Report of the President's Council of Economic Advisers: A Review

By CARL F. CHRIST*

The Economic Report of the President is of necessity a somewhat schizophrenic document. This is so because the Employment Act of 1946 (which called it into being) ordains that it seek to serve two purposes that are not entirely compatible.

On the one hand, it is an apology for the President's economic program, prepared by the President and a Council of Economic Advisers appointed by him for no fixed term. In this role, it seeks to show that the economic policies of the President and his party will be successful (and, if the incumbent president has already been in office for a year or more, have already begun to be successful) in solving the grievous problems created by the foolish mistakes made by the other party when it was last in power.

On the other hand, it is a professional economic report on the American economy and related public policy, prepared by three leading professional economists. These three economic advisers are chosen from among those who have devoted their previous careers (and will in all likelihood devote their subsequent careers) primarily to teaching and/or research in economics. In this role, the Economic Report seeks to present to the Congress and the public an analysis that is competent by the standards of the economics profession, describing and assessing the present state of the American economy, how it came to be the way it is, and how it can and cannot be changed by public policy especially at the federal level.

I believe this schizophrenia is unavoidable, unless the rules are changed either so that the President has no professional economists as advisers, or so that an independent body of professional economists is constituted and charged with issuing reports on the economy and public policy without being responsible to any elected official. Neither of these changes in the rules would be desirable. The first would deprive the President, the Congress, and the public of the competence and discipline offered by professional economic standards. The second would divorce the President's economic advice from the different but equally important discipline of the political arena.

The 1973 Report, like its predecessors from 1949 onwards, consists of three very different components. The first is the "Economic Report of the President" proper, addressed to the Congress and signed by the President. Mr. Nixon's 1973 report, like his 1972 report, is just 5 pages long.

The second is the "Annual Report of the Council of Economic Advisers," addressed to the President and signed by the Council. The 1973 version, by Herbert Stein, chairman, Ezra Solomon, and Marina v.N. Whitman, is 174 pages long, including two appendices. It is in this second part that the schizophrenia is most evident.

The third is a statistical Appendix, con-

* The Johns Hopkins University. I am indebted to my colleagues, Louis Maccini and Jürg Niehans, for valuable comments on an earlier draft, and to Mary Anne Matthews for drawing Figure 1.

sisting this year of 94 tables occupying 113 pages, giving a wide variety of economic data for the United States going as far back as 1929.

I. The "Economic Report of the President" Proper

Mr. Nixon's report begins with a review of the good things about 1972: a $7\frac{1}{2}$ percent rise in real output, a reduction of the inflation rate (measured by the consumer price index) to about 3 percent from about 6 percent in 1969, and a reduction of the unemployment rate to 5.1 percent in December 1972 from 6 percent in December 1971. But then his report seems to try to make the employment gain look better than it really is by saying that employment ". . . rose by 2.3 million people from 1971 to 1972, the largest 1-year increase in 25 years" (p. 3). This is true, but hardly remarkable when one notes that the labor force has been growing every year. A more correct impression would be given by saying that the *percentage employed* rose by 0.7 points (from 95.5 to 96.2 percent of the labor force), the largest one-year increase in 6 years.

Mr. Nixon's report sets forth domestic goals for 1973: "Output and incomes should expand. Both the unemployment rate and the rate of inflation should be reduced further, and realistic confidence must be created that neither need rise again. The prospects for achieving these goals in 1973 are bright—if we behave with reasonable prudence and foresight" (p. 4). And "We must prepare for the end of wage and price controls, . . . " (p. 6). This is reminiscent of Mr. Nixon's statement in January 1969, shortly after taking office, that he would reduce inflation without increasing unemployment and without imposing wage and price controls.

One of the most severe difficulties attending economic policy today is that the public has come to expect government to accomplish things that are impossible. It is unfortunate that Mr. Nixon, by such statements as the foregoing, makes this difficulty worse. The evidence strongly suggests it is not possible for the American economy, structured as it has been since World War II, to achieve simultaneously unemployment rates that remain at $4\frac{3}{4}$ percent or less, and consumer price increases that remain at $2\frac{1}{2}$ percent a year or less, without wage or price controls. In the 25 years since consumer prices leveled off at the end of World War II, this has been achieved in only 4 years: 1952, 1953, 1955, and 1965. See Figure 1. In those same 25 years, the average unemployment rate was 4.8 percent, and the average increase in consumer prices was 2.4 percent a year (these data come from Tables C-24 and C-50 in the Appendix of the Report). Virtually every other industrial country finds the same unwanted guest, inflation, at the banquet of full employment. This is not to say that there is any long-run tradeoff between unemployment and inflation: Chile, for example, has experienced inflation rates as high as 80 percent a year in recent years, with unemployment rates not greatly different from those in the United States. On the other hand, several European countries, with only slightly more inflation than the United States, have had far lower unemployment rates.

If the American public insists on keeping the unemployment rate below 5 percent at all times, and on keeping the consumer price index from rising faster than $2\frac{1}{2}$ percent at any time, with no fundamental changes in the structure of the economy, then wage and price controls will be a necessity. However, no major industrial democratic country has been able to impose effective wage or price controls in the face of substantial inflationary pressure without creating black markets, inefficiency, misallocation, and widespread frustration. And neither the United States nor

any other such country has been willing to tolerate controls and their consequences in peacetime for very long. Hence the evidence strongly suggests that it is not possible for the present American economy simultaneously to keep unemployment below 5 percent, and to keep consumer price increases at or below 2½ percent a year, *even with controls*, because the public will not tolerate controls and their consequences for long. At this juncture, when people believe that government can do things that cannot be done, we may possibly try a system of controls, but we will not maintain it for long.

It is not clear whether there is a feasible change in the structure of the American economy that will make it possible to keep unemployment below 5 percent and inflation at or below 2½ percent at all times.

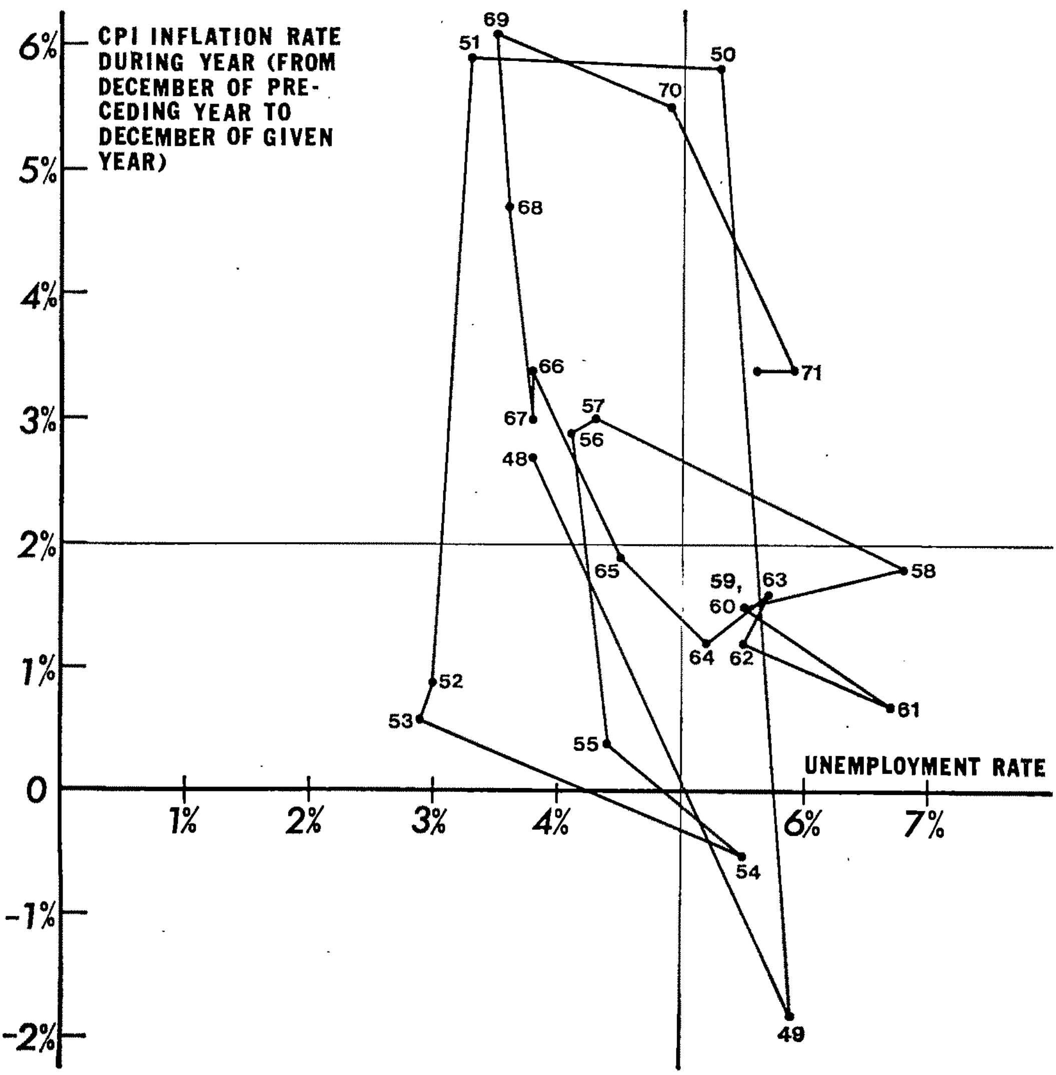

FIGURE 1. INFLATION RATE VS. UNEMPLOYMENT RATE, 1948–72

It has sometimes been proposed (not in the Economic Report) that the largest firms and unions be required to divide into smaller units, with a view to increasing the competitiveness of the economy, but I know of no persuasive evidence that this could accomplish the desired result. Proposals have also been made for better manpower training and job market information.

In my opinion, it would be far better for the President and other national leaders to set forth only goals that are achievable. Then citizens would be less likely to demand government actions that they will regret later (such as the imposition of controls), and more likely to try to solve for themselves problems that government cannot solve for them, and less likely to turn out of office able public officials who have committed no fault except the failure to accomplish the impossible.

Mr. Nixon's report goes on to advocate his well-known ceilings on federal budget expenditures: $250 billion for fiscal 1973, and $268 billion for fiscal 1974. (Even with those ceilings, projected budget deficits for those two fiscal years are $24.8 billion and $12.7 billion.)[1] It urges that government spending proposals be examined by asking whether they are worth their costs, and says "Much Government spending fails this test" (p. 4). This is the Report's only advance indication of the large-scale program cuts that have since been unveiled.

Mr. Nixon's report then outlines his price stabilization proposals for 1973. It summarizes Phase III's easing of wage and price controls except in food, construction, and medical care; asks for a one-year extension of the Economic Stabilization Act (which he opposed in 1970, and said he did not need and would not use); and details several steps already taken to increase food supplies: the suspension of meat import quotas, the relaxation of crop acreage restrictions, the increase in allowed imports of dried milk, the elimination of subsidies on farm exports, and the allowing of cattle grazing on land that has been diverted from crops. (Why were not oil import quotas removed at the same time, or even earlier, instead of later?)

The international economic policy section of Mr. Nixon's report is a plea for the international payments reforms proposed by the Administration in 1972 (described later in the Council's Report), and for support for the Administration's position in the prospective trade negotiations of 1973, laudably couched here in terms of the mutual advantages of free trade and payments.

Mr. Nixon concludes his report with the prediction ". . . that 1973 will be another very good year for the American economy." And that, if we do not exceed the increases in federal expenditures that he has proposed, "It can be a year in which we reduce unemployment and inflation further and enter into a sustained period of strong growth, full employment, and price stability" (p. 7). There go those pernicious promises of the unattainable, again!

II. The "Annual Report of the Council of Economic Advisers"

The Council's Report contains five chapters, entitled "The 1972 Record," "Inflation Control Under the Economic Stabilization Act," "Outlook and Policy," "The Economic Role of Women," and "The International Economic System in Transition." The chapter organization is virtually identical to that in the 1972 report, except that the chapter on women replaces a chapter on microeconomic policy. Appendix A gives supplements to chapters 2, 4, and 5, and Appendix B gives the now

[1] Secretary Shultz announced in May that the faster-than-anticipated rise in money incomes and tax revenues since January had led to a decrease in these projected deficits to $19.8 billion and $5.7 billion, respectively.

traditional listing of all past members of the Council since its beginning in 1946, together with the names of all who served on its staff during the year, and an account of the responsibilities and activities of the Council during the year. Appendix C, containing 94 statistical tables, will be reviewed in Section III. The text has 33 tables and 13 charts.

So many abbreviations are used throughout the text of the report, albeit usually with definitions the first time they appear, that an index might be useful. I offer the following, with the page number where the definition is to be found in each case: *CIEP* 120, *CISC* 60, *CLC* 79, *CPI* 30, *EC* 117, *EEOC* 111, *ESP* 143 (this doesn't mean extra-sensory perception), *FNMA* 49, *GATT* 128, *GNMA* 49, *GNP* 19, *HUD* 84 (not defined), *IMF* 121, *IRS* 146, *JEC* 182, *MFN* 133, *NIA* 19, *NTB* 133, *OECD* 136, *OMB* 181, *Quadriad* 181, *RPD* 45, *SDR* 114, *snake* 117, *TLP* 55, *Troika* 181, *T-2* 181, *T-3* 181, *tunnel* 117, *WPI* 30.

Chapter 1 gives a very informative account of the course of the economy and federal economic policy in 1972. On the whole, it is objective and sets a good standard for material directed to a nonprofessional audience, but on a few occasions statements are made that tell the truth, and nothing but the truth, but not the whole truth, in a manner that might be intended to put the Administration's performance in a favorable light. Here is an example. On page 30 we find this paragraph:

> In the period since the August 1971 policies were instituted there has been a dramatic deceleration in the rate of inflation. This is discussed in detail in Chapter 2; here we focus mainly on price measures applicable to the GNP. For example, the implicit price deflator for GNP, which measures the change in prices of all goods and services included in the gross national product, rose at a rate of 5.2 percent per year in the 3 years ending in the second quarter of 1971, the last full quarter before the policy shift. Over the next 6 quarters, the annual rate of increase was down to 2.7 percent.

This is true, but it creates the incorrect impression that there was an abrupt decline in August 1971, or thereabouts. Actually, the peak rate of increase in the *GNP* deflator, 6.5 percent, was attained in the first quarter and again in the fourth quarter of 1970, and by the second quarter of 1971, before the policy shift, the rate of increase had fallen to 4.4 percent (these are seasonally adjusted annual rates from Table C-4 in the Appendix). And the peak yearly increase in the *CPI* was in 1969. Hence a substantial decline in the rate of inflation had already occurred before the August 1971 policy shift.

Table 13 and Chart 5 point out that the share of interest plus profits before tax (after adjusting to a uniform method of calculating depreciation) in the gross product of nonfinancial corporations declined from 21 percent in 1950 to 17 percent by 1954, fluctuated near 17 percent through 1968, and fell to between 13 and 14 percent in 1970–71–72. The share of interest grew from about 1 percent to about 3 percent over the period, so that the share of profits alone fell from about 20 percent to between 10 and 11 percent. This is broadly consistent with the decline in corporate profits before tax as a fraction of *GNP*, from 13 percent in 1950 to about $7\frac{1}{2}$ percent in 1972. To put this in perspective, note that 1950 had the highest value for the share of corporate profits before tax in *GNP* over the period for which annual national income accounts are available (1929–72), and the figure for 1929 was 10 percent.

Chapter 1 discusses fiscal policy in the usual way in terms of federal receipts and expenditures, and monetary policy in the usual way in terms of interest rates and the changes in the stocks of money, time

deposits, and *RPD*'s (reserves available to support private nonbank deposits). It is useful also to link fiscal and monetary policy together by means of the government budget restraint, which provides that federal expenditures must be financed by some combination of tax revenues, borrowing from the private sector (including state and local governments and the rest of the world), printing new high powered money (which is done by borrowing from the Federal Reserve), and dipping into Treasury stocks of financial assets. It is useful to consolidate the Treasury and Federal Reserve sectors, so that their claims against each other cancel out. Then a Federal Reserve open market purchase or sale is treated just like a Treasury retirement or issue of debt vis-à-vis the private sector. The government budget restraint then implies that the federal deficit during any period must be equal to the following: the increase in the high powered money stock, plus the increase in federal debt held by the private sector, minus the increase in member bank borrowings from the Federal Reserve, minus the increase in *U.S.* reserve assets including gold, minus the increase in Treasury deposits at commercial banks, plus a small balancing item consisting of the increase in all other net claims of the private sector against the consolidated Treasury and Federal Reserve sector. For calendar 1972, the amounts are as follows, in billions of dollars:

deficit		increase in high powered money		increase in federal debt held privately		increase in member bank borrowing
17.4	=	4.3	+	14.6	−	0.9

	increase in U.S. reserve assets		increase in Treasury deposits		increase in other net claims against Federal sector
−	1.0	−	0.1	+	0.5

This means that the federal deficit of \$17.4 billion in calendar 1972 was financed chiefly by borrowing \$14.6 billion from the private sector (thus increasing privately held federal debt by 5.9 percent from \$247.9 billion to \$262.5 billion), partly by issuing \$4.3 billion of new high powered money (thus increasing the high powered money stock by 5.1 percent from \$83.8 billion to \$88.1 billion), and the negative remainder by a \$1.5 billion decrease in other net claims against the federal sector. The fact that reductions in reserve requirements in November released about \$3 billion of reserves made it possible for the money stock to increase by \$20.1 billion, or 8.3 percent, from \$242.8 billion to \$262.9 billion. (These data are from the *Federal Reserve Bulletin* for February 1973, and incorporate the revised figures for money and reserves published therein.) The projected deficits of \$12.3 billion for the six-month period ending in June, 1973, and \$12.7 billion for the fiscal year 1974,[2] presage either tight money if they are financed by borrowing from the private sector, or more inflation if they are financed by the issue of additional high powered money (unless reserve requirements are increased). If none of these alternatives is acceptable, then the deficits must be reduced either by limiting spending even more than proposed by Mr. Nixon, or by increased tax revenues.

Chapter 2, and the appurtenant section of Appendix A, constitute the report on economic stabilization activities that is required by the Economic Stabilization Act as amended. Its treatment of the effectiveness of the Phase I and Phase II controls is more balanced than that of chapter 1. Its main points are that although by August 1971, the rate of inflation had declined from its 1969 peak, and output and employment was expanding,

[2] But recall the revised projections mentioned in fn. 1.

it was uncertain whether the rate of inflation would continue to decline or would again accelerate (pp. 51–52); that if inflation did accelerate again the price increases would not be the direct result of excess demand but would occur because firms and workers preferred raising wages and prices since others had been doing so (pp. 52–53); that controls were necessary on a temporary basis to reduce the risk and the fear that the rate of inflation would rise or not decline further (p. 53); that the controls should be combined with initially expansive but gradually more restrictive fiscal and monetary policy because controls would not in fact be able to hold down prices and wages if there were strong excess demand, and the effort to do so would result in shortages and distortion of production (pp. 53–54); that the controls should be temporary because the Administration expected that if the total package of policies were well managed it would be possible to enter a period of reasonable price stability without controls (p. 54); that the rate of inflation of prices and wages did decline significantly during the controls period (pp. 56 and 58); that the Council believes it is probable that the controls did reduce the rate of inflation, but the magnitude of the reduction is uncertain, and one cannot be sure that the controls had an effect on the rate of inflation (pp. 61–62); that the controls were valuable in any case because they reduced the risk of inflation and reduced expectations of future inflation (pp. 62–63); and "Moreover, what had happened was not merely a suppression of price increases that would burst out if controls were removed" (p. 68).

This chapter's theory of the operation of wage and price controls in 1971–72 appears to be as follows (see Figure 1): in 1966 through 1970, inflationary expectations grew and created inflation without serious excess demand; by 1971 and 1972 there was substantial excess supply, but inflation would have (or might have) continued anyway based on expectations built-up previously; controls reduced the inflation rate by damping expectations about future inflation, without creating shortages or misallocation; controls could then be relaxed in 1973 and dropped later without leading to further inflation or unemployment, because expectations had been restored to normal by the end of 1972. I believe a series of events like this could certainly occur, provided that the control period is long enough and has sufficient excess supply so that inflationary expectations are indeed destroyed, and provided that the levels of inflation and unemployment to which the economy is expected to return after its inflationary binge are simultaneously maintainable. But neither of these provisions has been met in this case.

In the light of events since the publication of the Report in January, two of the statements in this chapter have turned out to be particularly inappropriate. One is on page 63: "By the end of 1972 the American anti-inflation policy had become the marvel of the rest of the world (Table 18) [comparing inflation rates among countries]. Largely because of this change the rest of the world is willing to hold increasing amounts of dollars." Hardly two weeks later, the dollar had been devalued again, and shortly after that attempts by other countries to support the dollar even at the devalued rate were abandoned. The other is on page 143: referring to the 1972 controls, the Report says "However, the temporary system had to be designed to avoid a price upsurge once the controls were removed or relaxed." Experience so far (in May 1973) with the relaxed controls of Phase III suggest that this design was not achieved.

There is a good description of the administrative regulations and procedures

used in implementing the controls. This should prove valuable if later on we need to remember the advantages and disadvantages of the methods adopted. The Report refers readers to the quarterly reports of the Cost of Living Council for more detail. The program cost about $80 million a year during Phase II, and employed about 4,000 persons, as compared with 60,000 during World War II, 15,000 during the Korean War, and about 2,000 during Phase III. The Price Commission received over 10,000 prenotifications of price increases, there were over 3 million inquiries from the public, and about 300 legal actions were undertaken for noncompliance under Phase II.

Prices charged by the federal government were exempted with the understanding that other means would be used to keep these prices consistent with the goals of the stabilization program. One wonders what those other means were, in view of the fact that from 1972 to 1973 the cash-and-carry price of the Economic Report was raised by 33 percent from $1.50 to $2.00, and the postpaid price was raised by 57 percent from $1.50 to $2.35.

The Administration's goals and the Council's forecasts are given in chapter 3, along with a discussion of the Administration's proposals to achieve its goals.

The Employment Act of 1946 calls for "... maximum employment, production, and purchasing power" (Report, p. 71). By common consent, price stability and balance-of-payments equilibrium have been added to that list of desiderata.

The stated goals are that unemployment should be down to the neighborhood of $4\frac{1}{2}$ percent by the end of 1973, and perhaps lower later, though this is not made clear (pp. 73–74), and that the rate of inflation should be down to $2\frac{1}{2}$ percent or less by the end of 1973 (p. 81). I have argued earlier that these two goals are not simultaneously attainable year after year, and that it is a disservice to announce them as if they were attainable.

The forecasts made for 1973 are as follows (pp. 82, 86, and 87). Nominal *GNP* for the year 1973 will rise 10 percent from the 1972 level of $1152 billion to $1267 billion; the chance that this prediction will err by more than 1 percent (i.e., that *GNP* will be less than $1254 billion or more than $1280 billion) is "extremely small." Nominal *GNP* will rise by 9 percent from $1196 billion in the 4th quarter of 1972 to $1303 billion in the 4th quarter of 1973. Real *GNP* for the year 1973 will rise $6\frac{3}{4}$ percent from the 1972 level of $790 billion to $843 billion, in 1958 dollars. The *GNP* deflator for 1973 will rise 3 percent from 145.88 in 1972 to 150.26. The *CPI* will rise $2\frac{1}{2}$ percent or less from 127.3 in December of 1972 to 130.5 or less in December 1973. The seasonally adjusted unemployment rate will decline from 5.1 percent in December 1972 to the neighborhood of $4\frac{1}{2}$ percent by December 1973.

Some of the Council's 1972 forecasts, from pp. 101 and 108 of the 1972 Report, and the actual outcomes, are as follows: Nominal *GNP* was forecast to be $1145 billion, low by $7 billion or 0.6 percent as compared with an actual $1152 billion. Real *GNP* was forecast to be about $784 billion, low by $6 billion or 0.8 percent as compared with an actual $790 billion, in 1958 dollars. The *GNP* deflator was forecast to rise $3\frac{1}{4}$ percent, high as compared with an actual rise of 3.1 percent. The inflation rate was forecast to be down to 2 to 3 percent by the end of 1972; in the 4th quarter the *GNP* deflator rose at an annual rate of 2.7 percent, and the *CPI* rose at an annual rate of 3.5 percent. The unemployment rate was forecast to decline to the neighborhood of 5 percent by the end of 1972; the actual rate in December was 5.1 percent. These forecasts were quite good, except for the year-end inflation rate which was somewhat underpredicted.

I wish I could believe the 1973 forecasts of unemployment and inflation, but for reasons given above, I cannot. Except for the Phase III controls, which are a watered-down version of Phase II, the Report offers no new departures in macroeconomic policy, and no reason to think that we can accomplish now what we have been unable to accomplish before.

Chapter 4, with the appropriate part of Appendix A, gives a highly informative account of the economic role of women. It is difficult to summarize, because there is so much detail. Among the important findings are these. The labor force participation of women is rising, in two respects: the participation of individual women in most age groups is rising as they become older, and furthermore, the participation of each cohort of women at a given age exceeds that of the previous cohort at the same age (Chart 9). The more education a woman has, the more likely she is to work, except that if she has children under 6 years old, she is unlikely to work regardless of her education (p. 95). Women change jobs less frequently than men, but spend fewer years at each job than men, because they leave the labor force more than men do, the most common reason being pregnancy (pp. 95–96). Black women have a higher labor force participation rate than white. Black married women earn about three-fourths as much as Black married men, while for whites the figure is about one-half, considering in each case only those who work full time the year around (p. 96). The unemployment rate is higher for women than for men, but the average duration of unemployment is less for women than for men; the apparent anomaly is explained by the fact that labor force entrants are unemployed for shorter periods than other persons, and women enter (and leave) the labor force more than men do (pp. 97–8). The differential in unemployment rates in favor of men has widened in the past decade, but part of this is due to a change in statistical concepts in 1967 (pp. 99–100). There has been a small reduction in the difference between the occupational distributions of men and women between 1960 and 1970 (pp. 100–03). Median annual earnings of women are about 40 percent of those of men; adjustments for differences in hours worked per week, weeks worked per year, age, education, experience, and continuity at work increase the ratio to 80 percent (pp. 103–06). The chapter concludes with a discussion of the problems of a woman who is the head of her household; difficulties in making the income tax treatment of women fair; the pros and cons of furnishing child care at public expense; and government programs to promote the economic equality of women.

Chapter 5 deals with *U.S.* international economic relations, and problems of the international trade and payments systems. This chapter begins with a brief account of *U.S.* balance-of-payments developments in 1972. The rest is a longer informative account of the recent history and current state of the international payments mechanism, and of the reform proposal put forward by the United States in 1972. Part of Appendix A is devoted to more detail on that proposal.

The Council says properly that an international monetary system must meet three requirements if it is to serve the needs of world trade and investment: it must be *market-oriented*, *multilateral*, and *stable*. And to be so, it must provide for the *adjustment* of payments imbalances, and for adequate international *liquidity*, and must create and maintain *confidence* in its continued viability and in the value of international reserves (pp. 120–21, Council's italics).

There are several references (for example, pp. 122, 131, 162) to the failure of the Bretton Woods system (with the dollar

pegged to gold, and other currencies pegged to the dollar) to provide adequate growth in the international reserves, and to the creation of *SDR*s ("paper gold") as a means of solving this problem. The Council does not take note of the fact that an alternative way of solving the liquidity problem would be to permit the money price of gold to rise. Since 1933, just before the United States increased the gold price to $35 an ounce, the official price of gold has risen by a factor of only 2.0 (from $20.67 to $42.22 per ounce), while the consumer price index, the wholesale price index, and the *GNP* deflator have risen by factors of 3.4, 3.5, and 4.0, respectively. At the time of this writing, the free market gold price stands at $91 per ounce, about 4.4 times the official 1933 level of $20.67. While it is by no means clear that $70 to $90 would be an equilibrium dollar price for gold if there were no international agreement to fix its price in transactions among central banks, neither is it clear that central banks and the *IMF* will be able to succeed in displacing gold as the main international currency in favor of paper currency such as *SDR*s. That depends upon the demand for gold among the world's asset-holders, including central banks, which will depend in part upon whether the new international paper currency is managed in a way that maintains its long-run values as compared with gold.

As for adjustment of payments imbalances, it is clear, from the fact of several dozen devaluations (and a few revaluations) since the Bretton Woods agreement was instituted after World War II, that exchange rates do require to be adjusted from time to time, whether the system is nominally one of fixed rates or flexible rates. It is not clear whether the day-to-day burdens of hedging against small changes in flexible rates are greater or less than the sum of the intermittent burdens of hedging against occasional large changes in fixed rates, plus the burdens of maintaining domestic policies that are undesirable for their own sake but are followed for the sake of defending a fixed rate in the face of market pressure against it. I lean toward flexible rates, except as between regions that have elected to have a common monetary and fiscal policy, such as the European Community countries have been in the process of deciding about for the past several years, and such as the United States in effect adopted in 1789. In my view, the fact that the Council and other high government officials can discuss exchange rate adjustment mechanisms on their merits is an improvement over the situation of several years ago.

The Council urges "innovations" which will permit to the United States the same margin of adjustment of exchange rates as to other countries, as contrasted with the Smithsonian agreement under which the dollar could not deviate from other currencies by more than $2\frac{1}{4}$ percent, while others could deviate from each other by as much as $4\frac{1}{2}$ percent (pp. 126–27). Presumably the innovations required would consist of pegging all currencies to gold, or to the *SDR*, or to each other as in the European Community, or not at all, rather than to any key currency such as the dollar was.

The Council properly takes a dim view of selective adjustment measures, such as tariffs, import surcharges, and quotas, and properly an especially dim view of quotas, since they permit the least amount of market response to changes in conditions. I would like to note that a sliding tariff, continuously equated to the difference between the domestic and world prices of a commodity, is nearly as bad as a quota, and should be discouraged by international agreement just as should quotas.

The Council supports the intent of the *U.S.* reform proposal, to devise means to press surplus countries to revalue, as a

counterpart to the natural pressure to devalue that deficit countries feel. (But where was *U.S.* zeal on this point in 1949 when *U.S.* reserves reached $26 billion, over half of the world's total?) At present this is a less pressing problem than it seems, because the need now appears to be more for an increase than a decrease in real international balances; hence every time a Japan or a Germany revalues in terms of gold and the *SDR*, the effect on *total* real reserves is pernicious because the total declines rather than increasing; it would be better for the required exchange rate adjustments to be made by the devaluation of overvalued currencies instead.

The heart of the *U.S.* proposal is that for each currency there should be established a theoretical "base level" of reserves, and also below that a "lower point," and above it an "outer point." Whenever a country's reserves fell below its lower point for a period of time, that country would be expected to devalue, and would suffer sanctions if it did not, unless the *IMF* decided (presumably in response to an appeal) that sanctions were not warranted. Similarly, whenever a country's reserves rose above its outer point for a period of time, that country would be expected to revalue, and would suffer sanctions if it did not, again unless the *IMF* decided that sanctions were not warranted (see pp. 124–25, 166–67). If the system were designed in such a way that the imposition of sanctions were highly uncertain in each case until the *IMF* had made its decision, it would be similar to both the Bretton Woods and Smithsonian agreements, except for its added pressure on surplus countries. However, if it were rigorously administered, so that countries passing their "lower" or "outer" points were all but certain to suffer sanctions and hence to be forced to devalue or revalue, with virtually no exceptions, then it might render international capital flows much more violent and severe than they are at present. For if everyone could rely nearly absolutely on, say, a devaluation of the dollar whenever *U.S.* reserves fell below the *U.S.* lower point, then whenever *U.S.* reserves approached the lower point there would be very heavy flows out of the dollar and into other currencies, thus assuring the devaluation of the dollar.[3] Speculation against a weak currency can only be stemmed if the speculators are not sure they will make a profit. Hence the advantages of the *U.S.* reform proposal would seem to be greater, the less vigorously it is applied.

III. Appendix C, Statistical Tables

For many readers, the 94 statistical tables in Appendix C are the most useful part of the Report. They constitute the cheapest, handiest, and most promptly available compendium of economic statistics on the *U.S.* economy that I know of. For many years I have acquired two copies of the Report, and kept one at home and the other at my office, so as to have a copy always at hand when I want to look up an economic datum. The tables cover national accounts; population and labor statistics; production indexes and other business activity measures; prices; money and credit; government finance; coporate finance; agriculture; and international economics.

Do not throw out the 1972 Report if you make extensive use of these statistical tables. This year, for the first time, the tables do not give the complete annual time-series since 1929, but give instead only the figures for 1929, 1933, 1939, and then every year since 1939. The purpose is to leave room at the foot of the page to show monthly or quarterly data for the most recent few years. Hence you will need to keep the 1972 Report alongside the

[3] I owe this point to Jürg Niehans.

current one in order to have complete time-series since 1929.

There are four new tables this year: C-4 gives several different versions of the *GNP* deflator, using different weights and concepts, and also shows percentage changes, year-to-year and quarter-to-quarter. Table C-11 gives nominal and real gross product originating in nonfinancial corporations, and nominal costs per unit of real gross product. Table C-33 gives percentage changes in output per manhour, unit labor costs, and the related data. Table C-47 gives seasonally adjusted consumer price indexes. The total number of tables is the same as last year; six of last year's tables (28–33) have been condensed into two of this year's (C-30 and 31).

IV. Concluding Remarks

I looked in vain for discussion of several economic problems that are generally regarded as among the most important facing the nation today. One is the welfare program, and alternatives to it. Since we have so far been unable to keep the unemployment rate below 5 percent, let alone $4\frac{1}{2}$ or 4 percent, and since we are unlikely to be able to do so in the future either, there will continue to be a function to be served by the unemployment compensation and welfare systems. The present welfare system has been widely criticized for many of its features, from its rapidly rising costs to the degree of effectiveness with which it meets the problems of poverty. Proposals for reform have been offered, and experiments have been conducted to learn about their effects. An analysis of these proposals, done as carefully as the Council's Report, would be a substantial contribution to public understanding and to an eventual solution of this vexing socioeconomic problem.

A second neglected issue is that of federal tax reform. The present federal tax system is unfair to the extent that it taxes unequally persons having the same incomes. The top-bracket personal income tax rate is now 70 percent. But few people having high income from property rather than from work pay this rate, or anything like it, for the present tax law contains many provisions permitting special favorable treatment of certain kinds of property income. Hence it is commonplace for a taxpayer who receives wages, salaries, dividends, and/or federal or private interest to pay a far higher tax than another taxpayer who receives an equal or even larger income from capital gains, oil and gas property, real estate development, certain foreign commerce, or interest on state and municipal bonds. Indeed, taxpayers who receive dividends are taxed twice, once via the corporate income tax, and again via the personal income tax. There are also important issues with respect to the estate tax and the gift tax. Mr. Nixon stated during his 1972 election campaign that he would present a tax reform package in January, and the Council's Report would have been an appropriate vehicle for it. (Secretary Shultz made a modest beginning when he presented the Administration's mild tax reform and tax streamlining proposals in May.)

Other important economic policy problems receiving little or no attention in the Report are environmental preservation, energy, health and health care, and the economic role and status of minority groups. To be sure, last year's Report discussed pollution control, energy problems, and health care. Nevertheless, these issues are no less important now than they were a year ago, to say the least, and since few people remember or go back and re-read old Economic Reports of the President, each new one ought to deal with the economic problems that are currently, or soon will be, of high importance.

The 1973 Report of the President's Council of Economic Advisers: Whistling in the Dark

By DAVID I. MEISELMAN*

The 1973 Economic Report is full of surprises, most of them disappointing. Among them is the apparent certainty of views, just before the storm, that inflation was tapering off and would continue to do so. For professional economists inured to the hazards of the forecasting trade, the Report contains several surprises of greater intellectual and academic interest. The first is the highly sophisticated analysis of the economic role of women. The second is one of the better briefs for the use of price and wage controls to stabilize prices, which is included in the Council's Report as a separate chapter. I share the judgment of Reuben Kessel, Edmund Phelps, Armen Alchian, and others who reviewed the Council's case for controls in the 1972 Report that not even the best case is good enough. Another surprise to many readers will be the strength and persistence of the Report's Keynesian bias, only partly explained by the Employment Act of 1946. The Report's discussion of government expenditures is not surprising but it is both noteworthy and by far the most rigorous and constructive part of the entire Report (see pp. 76–78). Achieving the required reduction of government expenditures and taxes implied by the discussion would truly be surprising.

The most disappointing aspects of the Report are the weaknesses and inconsistencies of its underlying analysis and its clever but faulty defense of and apologia for Phase I and II wage and price controls. Admittedly, the Nixon Administration did have some bad luck because of poor weather and the like. With the safety and wisdom of hindsight, it is now abundantly clear that the economy was excessively stimulated in 1972. As usual, the expansion of aggregate demand affected output and employment first and prices only later. No doubt, the improved economic performance of 1972 plus the control program, or the appearance of one, helped deprive the Democrats of important issues prior to and during the 1972 presidential campaign. By 1973, we had overshot the mark. Inflation had been ratcheted up to a new and higher trend. As before, slowing the accelerated inflation is bound to be costly. The goal of stable prices is more distant and more difficult to attain.

Errors in forecasting inflation are inevitable given the limitations of our understanding of how short-period changes in nominal *GNP* are divided between changes in prices and changes in output. Errors of prediction resulting from unavoidable ignorance and the poor state of the art may explain poor forecasts and help to excuse some of them. They need not lead to biased results for the latter require a corresponding inflationary bias on the part of policy makers.

* Professor of economics, Virginia Polytechnic Institute and State University. I received helpful comments from Gottfried Haberler, Wilson Schmidt, Deane Carson, and William Rule.

In my judgment, the 1972 overstimulation is much more serious than still another forecasting error because it is added evidence regarding the strong and inherently inflationary bias of virtually all modern governments. The bias is the result of a combination of factors which have increased the incentives and the technical means for governments to cause inflation at the same time that the constraints on their abilities to do so have been severely weakened. The bias increases in election years. For those in or close to the seats of state power, the costs of paying the piper fall sharply after a successful election day. The myopia of voters, including those with Ph.D.'s in economics, makes the game possible. Are we destined to add to our list a new cycle with a periodicity of four years?

There were impressive economic gains in 1972 in higher output and employment and lower rates of inflation and unemployment. Readers will find the good economic performance of 1972 attributed to the New Economic Policy of August 15, 1971. It combined controls aimed at curbing inflation with an expansionary fiscal policy in the form of both tax reductions and "... boosting Government expenditures in the first half of 1972, mainly by bringing forward expenditures that would have been made later" (p. 4). Although the 8.3 percent growth in money during 1972 was the highest of any year in the post-World War II period, monetary policy is taken to have been essentially passive and accommodating both because of the general stability of interest rates and the fact that nominal *GNP* increased somewhat faster than money did. Thus, a literal reading of the Report should provide much comfort to orthodox Keynesians and Federal Reserve traditionalists by allaying their fears that the Nixon Administration had become captives of the Monetarists, or had even seriously listened to them during 1972.

Consistent with President Nixon's earlier announcement that he had become a Keynesian, the Administration essentially followed the policy of its political opponents by relying on strong stimulation of aggregate demand to lower unemployment and Phase I and II controls to lower inflation. For a short time, it seemed to work.

The fact that much of the Report was soon overwhelmed by events palls the usual self-congratulatory tone of what has become part of the annual ritual of the Economic Report. For example, on the eve of the sharpest spurt of inflation since at least the Korean War and less than a month before the 10 percent devaluation of February 12, the Annual Report of the Council of Economic Advisers noted, "By the end of 1972 the American anti-inflation policy had become the marvel of the rest of the world. . . . Largely because of this change the rest of the world is willing to hold increasing amounts of dollars" (p. 63). The Council's forecast, which did so well in 1972, quickly became a shambles early in 1973.[1]

The poor forecasting performance of the Report cannot be attributed to analytical innovations that did not pan out. In my judgment, one of the deficiences of the Report is that it conforms mainly to the format and the content of the Council's analyses of yesteryear. Its framework is the simple Keynesian model. The Report largely ignores how thoroughly the model

[1] The embarrassment has been both bipartisan and virtually universal. For example, sharing the optimism of the Republican president, Walter Heller crystal-balled the 1973 *GNP* deflator as rising only slightly to 3-1/3 percent from the 3 percent rate of 1972 as part of a strong expansion ". . . without fatal flaws of malfunctions" (*Wall Street Journal*, Jan. 11, 1973). The large file of *GNP* forecasts I collect shows that not a single published forecast came close to calling the shots on the inflationary outburst in the first half of 1973 and the 8 percent increase in real *GNP* in the first quarter.

has been modified, both by a vast body of scientific evidence and analysis and by repeated failures of past public policies that depended upon it. The Report also generally overlooks the rich and important advances in recent years in establishing the close connections between micro- and macro-economics. In particular, it underplays the central roles of relative prices, lags, and adjustment processes in short-period fluctuations in helping to explain labor market phenomena such as employment and unemployment. The Report's annual review of the 1972 labor market is devoid of analysis and is largely a verbal repetition of the numerical contents of several standard tables in the *Monthly Labor Review* describing employment, unemployment and labor force participation. The Report would have been greatly strengthened if the highly sophisticated and informative analysis of the economic role of women had been applied to the remainder of the population. Reverse discrimination is also costly.

The review and outlook chapters have typically been the central features of Council reports. The 1973 Report follows this tradition. The review chapter has five sections plus a short postscript on fourth quarter 1972 developments. The five sections are devoted to "Demand and Output," "The Labor Market," "Prices and Costs," "Fiscal Policy" and "Financial Policy and Financial Markets."

Following another tradition, the underlying macro theory is never clearly or explicitly spelled out, but reading the entire chapter does suggest the general outlines of one. Nominal *GNP* is taken to be mainly determined by private expenditures for business fixed investment and for housing construction, both of which have responded to tax incentives, financial variables and autonomous factors, all expansionary in 1972. Nominal consumer spending (i.e., personal consumption expenditures) is induced by the resulting general improvement in the economy. Reference is made to the fact that consumers "made extensive use of credit to finance their purchases, particularly of durable goods" (p. 23), but it is not clear whether the quantity of credit (no cost is mentioned) is the result of the increase in consumer outlays or a cause. Government expenditures are considered in their full employment budget context. The chapter on the 1972 record has no accounting for foreign trade, which is treated in a separate chapter essentially unrelated to the *GNP* accounts.

Aggregate nominal demand is also related to fiscal policy, mainly as evaluated by high employment federal government expenditures and receipts. The net stimulus is taken to be the change in the high-employment deficit. In this view, changes in nominal high employment expenditures and receipts have equal and opposite effects, modified slightly by a permanent-income hypothesis view of temporary changes in tax cash flow, such as the 1972 overwithholding.[2] Only the federal budget is considered.

The emphasis on the two major components of gross private domestic investment (the change in inventories is omitted) overlooks the facts that the empirical association of total investment and *GNP* is poor indeed, and that there are important differences in the timing of the business investment and housing expenditure components. Despite continued emphasis by most business forecasters in government and elsewhere on the role of business investment expenditures in determining

[2] In the Economic Report of the President, President Nixon's statement about the federal budget emphasizes both the inflationary and allocative effects of federal government expenditures and so is not entirely in agreement with the Council's stated view. Apparently, in his view, a large budget per se is inflationary.

GNP, it turns out that these outlays typically follow rather than lead the business cycle. Indeed, business expenditures for new plant and equipment are a lagging indicator! By contrast, expenditures for residential structures lead the cycle.[3]

Collateral emphasis on the size of the federal deficit in controlling *GNP* ignores the empirical studies of Friedman-Meiselman, Andersen-Jordan, and others which bring into serious question the keystone of the fiscalist analysis and the efficacy of policy proposals stemming from it. The Andersen-Jordan results are consistent with President Nixon's assertion cited above about the expansionary impact of the sharply higher level of federal government spending in 1972, but recall that this works only in the very short run. When money is held constant, an increase in full employment expenditures temporarily increases *GNP*, but later causes *GNP* to decline. Within a year the net effect is essentially zero. The expenditures merely cause an intertemporal shift in the total.

Even within the analytical and empirical framework that attributes an important role to government expenditures and taxes, it would seem that the general omission of state and local budgets is a serious deficiency. Analyzing government on a consolidated basis, following the practice used in the consolidated government receipts and expenditures account of the national income accounts, is highly desirable, indeed, necessary. State and local government expenditures are huge indeed, and have been growing even more rapidly than the federal government's. By 1972 state and local government expenditures on the national income accounts basis were $162.9 billion, or almost 80 percent of the $209 billion for federal expenditures net of grants to state and local governments. Similarly, focusing solely on the federal deficit or surplus can also be highly misleading. In 1972 the federal deficit on the national income accounts basis (net of grants to state and local government) was $18.5 billion. The federal high employment budget deficit was $6.0 billion. In 1972 state and local governments recorded a *surplus* of $12.3 billion on a national income accounts basis. We are left to wonder whether government, on net, was exercising restraint or providing stimulus during the year, especially in the fourth quarter of 1972 when revenue sharing sharply increased both the deficit of the federal government and the total surplus of state and local governments.

Monetary policy appears to be evaluated by two criteria. The first, and more traditional, indicator of monetary policy is interest rates and credit market conditions. The rate of interest is essentially taken to be determined by the demand for and supply of cash, with resulting interest rates modified somewhat by expectations of future inflation and interest rates. "Accommodating" is never defined, but whatever it means, monetary policy in 1972 is viewed as having been accommodating because of the general stability of nominal interest rates. The source of the expansion was elsewhere. The Federal Reserve can claim credit only for not having pulled on the string.

There seems to be a second indicator of monetary policy which is more novel, but no more apt. Other evidence for the Fed's having taken an accommodating rather than active role is presented by citing the fact that the money supply increase of 8.2 percent (later revised to 8.3 percent) was less than the expansion of 10.9 percent in nominal *GNP*. This is a position which has been publicly shared by Arthur Burns, Chairman of the Federal Reserve Board. In other words, the fact that income velocity rose slightly during the year, as it typically does during business cycle ex-

[3] See *Business Conditions Digest*.

pansions, is interpreted as support for the contention that monetary policy was essentially passive in 1972.

I also find it difficult to understand how velocity can be used as an indicator of monetary policy. The Fed may directly control the stock of money, but surely it is the public's demand for cash that determines the ratio of money to *GNP* or the response of *GNP* to a given change in money. To suggest that a central bank can treat velocity as subject to its direct control or that it can effectively treat velocity as a target or indicator of monetary policy is similar to but no more valid than the view that it can control real balances.

The novel proposition raises some interesting questions. Consistent with this view would it be correct to infer that the central bank was merely being accommodating in a mythical country which had experienced a doubling of money accompanied by a 120 percent increase in nominal *GNP* or prices? Would a 200 percent increase in prices associated with *GNP* growing still faster than money have been more accommodating or less? Alternatively if, as in the early 1930's, velocity falls when *GNP* declines faster than a central bank has contracted money, does this imply an expansionary monetary policy? What of constant velocity?

Although the Report cites "remarkably mild increases in short-term interest rates," the record is that short-term rates did, in fact, rise sharply and almost continuously throughout the year. Early in 1972, short-term rates had been falling since mid-1971. The low point was reached in February 1972, when 3-month Treasury bills yielded 3.18 percent on average. By December 1972, the average new issue yield had risen above 5 percent. (By March 1973, bill yields were above 6 percent.)

However, the important point is not that short-term rates and income velocity rose, but that there was an 8.3 percent increase in M_1 during 1972. (M_2 increased 10.8 percent.) The monetary base, which is clearly under the direct control of the Fed, also increased by the same 8.3 percent. The base multiplier remained virtually constant throughout the year. Money increased so rapidly precisely because the Fed increased the monetary base. In my judgment, the Federal Reserve bears a large share of the responsibility for the 1973 acceleration of inflation. They blew it again.

The discussions of monetary policy ("Financial Policy and Financial Markets") and of fiscal policy are unrelated, reflecting the lack of unity in the Report as a whole. There is no explicit consideration given to any possible relationship or tradeoff between fiscal and monetary policy, the impact of fiscal policy on interest rates and financial markets and perhaps thereby on resource allocation, the balance of payments, and the like. No mention is made of debt management, a commendable move towards its deemphasis.

The outlook and policy chapter has several guides to the use of fiscal and monetary policies for reaching the potential growth rate of the economy and reasonable price stability by means of a steady increase in nominal *GNP*. For fiscal policy the Report recommends the general rule of achieving and maintaining balance in the full employment budget of the federal government:

> . . . desired . . . steadiness of the rate of increase of money GNP would be assisted by keeping the budget in a position of balance at full employment, unless there later appears clear and strong evidence that developments in the private sector call for greater fiscal stimulus or restraint. Constancy in the relation between full-employment receipts and expenditures provides approximate constancy in the Federal contribution to economic expansion. The constancy of the contribution is only approximate

> because the impact of the budget on the economy depends on its composition and total size as well as on the size of the deficit or surplus. However, constancy of the balance at full employment is the best single guide to a budget policy that neither pushes the economy above its desired growth rate nor holds the economy below it. In any case, the rule that expenditures should not exceed the revenues that would be collected at full employment is essential to bring home the requirement that Government should not spend money for things it is unwilling to ask citizens to pay for. The circumstances of 1973 are appropriate for getting on to that track. [p. 74–75]

The statement does not agree with the Report's companion assertion:

> . . . experience has shown that the proper conduct of macroeconomic policy may sometimes call for a prompt and effective shift in the overall balance between the flow of Federal receipts and expenditures. Temporary and prompt changes in tax rates, which do not alter the basic structure of taxes, may provide an efficient way of accomplishing such required shifts. [p. 75–76]

You obviously can't have it both ways. Moreover, evidence both from the imposition of the 10 percent surtax in 1968 and its removal in two steps in 1969 and 1970 as well as from large numbers of independently replicated statistical tests indicate the weakness of this and related fine tuning tax measures.

For monetary policy, the Report proposes monetary growth at a steady but unspecified rate. This recommendation is inconsistent with the Report's earlier discussion of monetary policy described above. No mention is made of interest rates or velocity as targets or indicators of monetary policy as the Report states:

> A gradual slowing down of the expansion of money GNP to a steady rate consistent with the long-run potential growth rate of the economy and reasonable price stability is also an approximate goal for monetary policy. This is likely to require a slower increase in the supply of money and credit than was proper when the main objective was to encourage the quickened economic expansion in an environment of substantial unused resources. [p. 75]

The parts of the Report devoted to inflation probably received the greatest care and have attracted the most attention. Students of inflation will find many theories of short-period changes in the price level. A variety of theories is understandable in view of the poorly developed state of economics in understanding short-period changes in the price level. Even so, some should be ruled out because of errors of analysis or because they have been contradicted by the evidence. I find that one of the two leading theories in the Report is simply wrong, and the other highly questionable.

One approach believes that the price level is determined by the costs (expenses?) of producing the goods entering the price index. This view confounds relative and absolute prices as well as *ex ante* and *ex post* values. The review section, "Prices and Costs," attributes the 1972 slowing of inflation to a ". . . marked deceleration in the rise in unit costs. For labor costs, this was a result of two factors: a slower rise in hourly compensation and an acceleration of the rise in output per man-hour. . ." (p. 31). It is not entirely clear whether the Report is presenting an identity or a behavioral relationship. National income is the factor expense of the *GNP*; the price level enters both sides of the accounting identity. Explaining one deflator by the other plus the change in productivity is essentially a tautology. Double entry bookkeeping being what it is, it is difficult to see how the result could be very different, especially in view of the stability of factor shares.

Another approach emphasizes the im-

portance of price expectations in contributing to the inflation itself. The general proposition has some merit, but not in the context found in the Report or in most current discussion. It should not be necessary to do so, but it bears repeating that inflation is a change in the value of money, not a change in the average of selected prices.[4] Moreover, changes in the price level are an important part of the general equilibrium process whereby the demand for money becomes equal to the supply of money. This is why there is essential agreement among all economists that for given real factors, including preferences, a once-for-all change in nominal money leads to a proportional change in the price level *in the long run.* For given real factors, velocity is constant. Prices adjust to change the value of real balances in order to reestablish the equilibrium where desired and actual real balances are equal. Because actual and anticipated changes in prices affect the perceived cost of holding cash, they must be included in the real factors determining velocity. Although the short-run dynamics are uncertain, the economy is nevertheless driven to the long-run norm.

In the short-period changes of the business cycle, links between money and prices are clearly looser, in part because income and other real variables change, in part because of lags in adjustment, and the like. These are some of the reasons the short-run analysis of price levels is so much more difficult and uncertain. Yet, a decline in the rate of expected inflation can itself lower velocity, moderating the inflationary potential of a given money stock. If, indeed, we knew how to alter inflation expectations, which we surely do not, we could have some impact on both velocity and interest rates. But if we really knew the effect on velocity we could more easily achieve the same goal by appropriately altering the money stock.

It is worth noting that in 1972 both velocity and short-term interest rates increased. If price expectations had been altered as substantially as the Report claims, how can we explain why both velocity and short-term rates moved in the wrong direction? Obviously, either price expectations did not really change very much and/or the impact of the altered anticipations was swamped by other factors. In any event, it suggests that the shift in expectations played a minor and uncertain role in the events of the year.

Comparing the discussions of price and wage controls in the 1972 and 1973 Reports, I found that the 1973 Report was unable to provide any additional economic arguments for them, except perhaps, at the time the 1973 Report was written, the 1972 deceleration of inflation gave the program some appearance of success. When reviews of the 1972 Report were written for this and other scholarly journals the Phase II controls program was already in place. I believe the critiques of Alchian, Kessel, and Phelps, with whose views I concur, read even better than when they were first written in the spring of 1972. Neither the 1973 Report nor the events subsequent to these reviews seriously challenge their contentions that the controls were, at the very least, disruptive, wasteful, discriminatory, arbitrary, costly —and ineffective.

Because the 1973 surge of inflation followed so quickly on the heels of the relaxation of Phase II controls, it will be difficult for the public not to draw incorrect *post hoc propter hoc* inferences that controls had been effective. Indeed, after the President and his economic advisers and spokesmen in and out of the Council of Economic Advisers had for so long attrib-

[4] For an alternative view, see the analysis of what I termed "The peanut theory of prices" (p. 745), in my 1968 comment.

uted so many good results to the controls, citizens are justifiably puzzled why the reluctance to go still further with even stronger measures. As the 1973 Report said, ". . . nothing seems more obvious than that the imposition of controls should curb inflation" (p. 63). The long and dismal historical record that price and wage controls can, at most, only appear to curb inflation temporarily appears to have been subordinated to the requirements that the Administration do something, even if the actions were detrimental to both economic efficiency and individual liberty.

The added defense, ". . . the controls had a symbolic value as evidence of the Government's determination to take whatever steps might be necessary to check inflation" (p. 63), may help to explain the symbolic acts of the executive branch of the federal government. There has clearly been a clamor for action, and controls give the appearance of action. In a democracy it is difficult, indeed, for any political leader this side of heaven to resist such demands, especially if, in the process, more power and discretion flow to him. I would like to believe the chain of events was not inevitable—that the only options were not between weak and tough controls, especially since I am convinced that there is little on the horizon to alter the worldwide inflationary bias.

Economic policy has suffered from a lack of leadership and candor. It is not too much to ask that the President whose leadership in foreign affairs made possible the first fundamental changes in Amercan foreign policy in a generation, who led the successful campaign to eliminate conscription, and who cut the dollar loose from the incubus of gold and fixed exchange rates, also exercise some of the same qualities of leadership at home.

The 1973 Report of the President's Council of Economic Advisers: A Critique

By MICHAEL PARKIN*

The record of the American economy in 1972 looked impressive. The major preoccupation, the rate of inflation, was reduced (as measured by the Consumer Price Index) from almost 5 percent in 1971 to a little over 3 percent by the end of 1972. This was achieved at the same time as the unemployment rate was being cut back from its 6 percent peak in 1971 to end 1972 at 5.1 percent, and as the real growth rate (as measured by constant price *GNP*) was being stepped up from its 1971 level of 2.7 percent to 6.5 percent. The prospects for 1973, as seen by the Council of Economic Advisers (*CEA*) in the Report point to an equally impressive performance. The inflation rate is seen as falling further to the region of $2\frac{1}{2}$ percent, unemployment as falling further to the $4\frac{1}{2}$ percent zone, and constant price *GNP* as growing by even more than in 1972 at about $6\frac{3}{4}$ percent.

The view of the Report is that 1972's successes were due to a combination of the skillful use of fiscal and monetary policy and to the wage-price controls associated with the Economic Stabilization Act amendments initiated on August 15, 1971. "Fiscal policy was deliberately expansionary in 1972" (p. 40) with stimulation coming from both spending increases and tax reductions. The money stock (narrow definition) grew at 8.9 percent on the year and short rates moved up from the low levels they attained in the middle of 1971 while long rates remained remarkably steady. This mix of expansionist fiscal policy, moderated slightly by firm (but not tight) monetary policy, is seen as having stimulated the increased real output and fall in unemployment. It is argued however (ch. 2) that, in the absence of the wage-price control program, this stimulation of nominal demand would have had a bigger effect on prices and less effect on real output and employment. Hence, the wage-price controls are seen by the *CEA* as an essential accompaniment to the fiscal and monetary reflation.

The predicted success for 1973 is seen as stemming from a slowing down of the growth rate of nominal GNP from 11 percent to 9 percent resulting from a shift of the budget from a position of deficit to one of balance at full employment, and from a ". . . slower increase of the supply of money. . ." (p. 75). The 9 percent growth in money *GNP* will be translated into a 6 percent (or more) real growth rate and a 3 percent (or less) inflation rate with the help of Phase III of the wage-price controls, the essence of which is ". . . that the Government retains the enforcement ability and authority necessary to the Nation's anti-inflation objective while leaving the private sector the maximum possible freedom to pursue productivity, efficiency, and collective bargaining" (p. 82).

In marked contrast to the successful

I am especially indebted to my colleagues Malcolm Gray, David Laidler, and George Zis for comments on an earlier draft.

developments of real output, employment, and the price level, the *U.S.* balance of payments remained in deficit in 1972. The balance on current account and long-term capital account was (on a provisional estimate) running at a $10 billion deficit for 1972. This is $1 billion worse than 1971 and $7 billion worse than 1970. The current account alone deteriorated by almost $6 billion during 1972. During this same period the international monetary system has undergone considerable turmoil and change. The Report sees the balance of payments improving during 1973, largely as the result of "... the dollar devaluation, reinforced by the lower rate of inflation in the United States than in other major industrialized countries in 1972, [which] is beginning to affect U.S. exports and imports" (p. 115) but admits that "... long-term changes in trade patterns have tended to make the elimination of the U.S. balance-of-payments deficit more difficult" (p. 116). A crucial ingredient in the solution to America's (and every other country's) balance-of-payments problem is the reform of the world monetary system. The Report presents the, by now, widely rehearsed American case for solving the liquidity problem by placing more emphasis on *SDR*s and for solving the adjustment problem by having greater two-way flexibility of exchange rates based on the objective criterion of reserve changes.

What questions are raised by this brief review of 1972 and preview of 1973 as developed in the Report? The most obvious question which arises concerns the role of the wage-price controls in the slowdown of the inflation rate. The success of American macroeconomic policy in 1972 has not gone unnoticed in other countries. In particular, the British are so enamoured of the American performance that they have set up a wage-price control program which replicates the August 15 *U.S.* measures. Also, discussions underway in Australia as the new Labour Government begins to tackle that country's inflation problem are being heavily influenced by America's recent experience.

The infectiousness of wage-price controls gives some urgency and importance to the question: what was the source of America's success? Did the controls contribute to the slowdown of inflation or was that slowdown entirely due to "... slowing down the rise of Federal spending and continuing the temporary tax increase that had been enacted in 1968 and by tightening monetary conditions" (p. 3). In view of the fact that some countries (again the *UK* in particular) are following the United States with wage-price controls but not with fiscal and monetary stringency, this additional question assumes considerable relevance. Further, there is some danger (hinted at by the Report)[1] that the *U.S.* reflation, which is now underway will, instead of gradually converging on a sustainable degree of resource utilization, overshoot and stimulate a further bout of inflation. If this happens, will a reactivation of measures similar to those used following August 1971 be adequate, or will the economy again have to be put into a 6 percent unemployment recession to get rid of the inflation? These questions are examined in Section I below.

A second set of questions which emerge concern the broad strategy being adopted towards fiscal and monetary policy and the execution of that strategy. Are the demand management policies which are being pursued well conceived and likely to lead to the achievement of "the basic mandate for policy set forth in the Employment Act ... to achieve 'maximum employment, production and purchasing power'?" This is looked at in Section II.

[1] Developments in 1973 have made this danger a reality.

Finally, what are the likely implications, with respect to employment and inflation of the international monetary reforms advocated by the Report? Would those reforms simply free policy making from the balance-of-payments problem, and in themselves, be neutral towards employment and inflation or will the attainable levels of unemployment and inflation be different as a result of introducing *SDR*s as additional reserve assets and adopting greater exchange rate flexibility between the major currencies? This is examined in Section III.

I. The Wage-Price Controls

Did the wage-price controls reduce the inflation rate below what it would have been in the absence of controls? The Report answer is a cautious "yes." It is argued that there are three pieces of evidence which lead to that conclusion. First, the ". . . econometric study of the relation between the rate of inflation and other variables, such as unemployment, prior inflation rates, and growth of demand. [shows that when] The relations derived from past experience are used to project what the inflation rate would have been in the absence of controls. . . . , the projected inflation rate . . . [is] larger than the rate actually experienced in 1972," (p. 61). Second, the distribution by size of wage adjustments in collective bargaining changed importantly between 1971 and 1972. In 1971 the distribution was bimodal with one mode (16 percent of settlements) in the 6–7 percent range and the other (53 percent of settlements) in the open ended 10 percent plus range. In 1972 the distribution became much more compressed and had a single mode (24 percent of settlements) in the 6–7 percent range.[2] Third, evidence from both public attitude surveys and from the behavior of interest rates indicate that inflationary expectations reduced more sharply in the months immediately after August 1971 and continued to decline during 1972 (pp. 62–64).

The first thing that we should note in attempting to evaluate the effects of the controls on the inflation rate is that, although a quarter by quarter explanation of the movements of wages and prices needs a quite sophisticated model, in broader terms, there is no mystery about the determinants of *U.S.* inflation. William Nordhaus has shown that, for annual data, the best simple explanation of the *U.S.* inflation seems to be provided by an expectations augmented Phillips curve.

Nordhaus's equation, estimated on annual data for 1956 to 1968, explains a very high proportion of the variance of the rate of wage change, pp. 443–46, has residuals which appear to be free from autocorrelation, has a coefficient which is not significantly different from unity on the expected inflation rate and predicts the 1969–71 wage change with remarkable accuracy.[3] This simple model has important implications for the cyclical development of inflation and unemployment. A version of the model may be written as:[4]

[2] See the Report, Table 17, p. 62.

[3] Nordhaus's equation is

$$\Delta ln\ w_t = -0.0172 + 1.962\ u_t^{-1} + 0.873\ \Pi_t^e$$
$$\qquad\qquad\qquad (0.371) \qquad (0.204)$$

where $\Delta ln\ w_t$ is the first difference in the natural logarithm of hourly earnings, u_t is the unemployment rate, and Π_t^e is the expected inflation rate (calculated as weighted average of past actual inflation). The figures in parentheses are standard errors. The standard error of estimate is 0.0062 and the *D.W.* 2.36. The prediction errors beyond the end of the sample period were:

1968	1969	1970	1971
+0.8	−0.2	−0.7	+0.6

(see Nordhaus, Table 9, p. 447).

[4] The particular form of the analysis presented here was developed by Herschel Grossman, and suggested to me in discussions with him on this subject. Qualitatively similar formulations are to be found in Edmund Phelps and in David Laidler.

$$(1) \qquad p = \lambda X + p^e$$

$$(2) \qquad p^e = \gamma p + (1 - \gamma) p^e_{-1}$$

where

p = actual rate of inflation
p^e = expected rate of inflation
X = excess demand (proxied by the inverse of unemployment)
$-i$ = time lag

We see that the change in the rate of inflation is given by:

$$(3) \qquad (p - p_{-1}) = \frac{\lambda}{1 - \gamma} X - \lambda X_{-1}$$

In words, the inflation rate rises or falls according to the values of the current and previous levels of excess demand. If excess demand is positive ($X > 0$) and the previous value was negative ($X_{-1} < 0$) then inflation increases. In other words, if the economy is moved from a position of excess supply to excess demand, the inflation rate rises. If, on the other hand, the economy moves from excess demand ($X_{-1} > 0$) to excess supply ($X < 0$), inflation falls. If excess demand is positive in two successive periods, i.e., ($X > 0$, $X_{-1} > 0$), then inflation rises or falls, i.e., $(p - p_{-1}) \gtrless 0$ as $\Delta X / X_{-1} \gtrless -\gamma$. That is, if excess demand falls, unless it falls by more than γ times its previous value, inflation still rises. On the other side, if excess demand is negative, $(p - p_{-1}) \gtrless 0$ as $\Delta X / X_{-1} \lessgtr -\gamma$. That is, with excess supply (negative excess demand), a rise in excess supply always lowers inflation but a fall in excess supply only lowers the inflation rate if it is bigger than γ times its previous value. These qualitative predictions seem to fit the *U.S.* economy almost exactly, provided we assume that $X = 0$ is associated with a 4.5 percent unemployment rate.

Table 1 sets out the annual behavior of the relevant variables in the *U.S.* economy since 1965. Excess demand was positive *and rising* in each of the years 1965, 1966, 1968, and 1969. In each of those years, as predicted, the rate of inflation increased. In 1967, excess demand was steady and the inflation rate was held steady (-0.4). In the years 1970 and 1971, excess demand was negative and increasing, so, and again as predicted, the inflation rate decreased in both years. In 1972, excess demand remained negative but moved closer to zero and the inflation rate steadied. The above analysis is, of course, purely qualitative and I would not want to press it in precise quantitative terms. Nevertheless, in broad terms, it suggests that the *U.S.* inflation—its build-up and gradual decline—can be explained by the movements in the pressure of excess aggregate demand as reflected in the unemployment rate. The question to ask about the wage-price controls then, is not did they reduce the *U.S.* inflation, but did they have any effect in addition to that of the level of aggregate demand?

TABLE 1—THE CHANGES IN INFLATION AND CHANGES IN UNEMPLOYMENT, 1965–72

	Change in Rate of Inflation (1)	Proportionate Change in Unemployment Rate (2)	Sign of Excess Demand	Predicted Sign of Change in Inflation Rate
1965	+0.7	−0.13	0	+
1966	+1.5	−0.16	+	+
1967	−0.4	0.00	+	0
1968	+1.7	−0.05	+	+
1969	+1.4	−0.03	+	+
1970	−0.6	+0.40	−	−
1971	−2.1	+0.20	−	−
1972	0.0	−0.05	−	?

Sources: The Report, Col. (1) Table C-50, p. 262; Col. (2) Table C-26, p. 223.

Let us examine the three pieces of evidence suggested by the Report. First, the econometric work. The only published econometric study seems to be that by Robert Gordon (1972). Gordon first compares his own earlier wage-price model

(1970) with those of Otto Eckstein and Roger Brinner and George L. Perry (1970) and finds his own model tracks the precontrols period better than either of the other two models. He then uses his model to simulate the period from 1971:IV to 1972:II and finds that, on the average during those *three* quarters, wages rose by 0.68 percent per annum and prices by 1.85 percent per annum *less* than the model predicted they should have done.[5] What are we to infer from this? First, of course, we must recognize that we are dealing with a simulated prediction which runs over only three quarters and from a model which, whilst it tracks 1955–71 quite well, is by no means a deterministic relationship. Indeed, the equations were predicting the change in prices in the post-sample precontrols period of 1971:I and II quite badly. The average predicted rate of price change for 1971:I and II was 3.91 percent per annum against an actual rate of 4.65 percent.[6] The prediction error was positive by 1 percent in 1971:I and by ½ percent in 1971:II.[7] Thus, the model was underpredicting price change just prior to the controls but by a decreasing amount. It would therefore be rash to attribute the overprediction during the three controls quarters as being entirely due to the controls.

Second, the fact that Gordon's results show a marked departure of the behavior of prices from that of wages, implying that the controls substantially reduced profit margins should give some doubt about the lasting effects of the controls on the inflation rate. If, over some period of control, two broad indices of inflation do not bear the same relationship to each other as they do on the average, in the absence of controls, then we must expect some compensating departure in the opposite direction, either later in the control period or when the controls are removed. In this case, we must expect some subsequent faster price rises *or* slower wage rises or a combination of the two to restore relative prices to what they would have been in the absence of controls. Whether the adjustment will come out in wages or in prices will depend largely on the monetary and fiscal position. The fact of controls is likely to encourage fiscal and monetary adventurism and therefore to put the economy into a situation such that wages will continue on their course with prices moving ahead more quickly to catch up to their precontrols relative position. Before this issue can be settled, a longer run simulation will be needed taking us through and beyond Phase II and into Phase III.

This evaluation of Gordon's econometric attempt to estimate the effects of the controls on the rate of inflation leads me to accept the view expressed by the Report that ". . . . evidence from this source must be regarded as inconclusive" (p. 61).

The second piece of evidence for the effectiveness of the controls advanced by the Report, which it seems to regard as more convincing than the econometric studies, is the distribution of wage changes in collective bargaining in 1972. I find the reasoning here throughly confusing and misleading. It is true that the distribution by size of wage change shifted downwards considerably between 1971 and 1972. However, the rate of wage and price inflation was also falling at that time, hence, the distribution must have shifted downwards! What is at issue is not the fact but the cause. If the 1972 distribution is compared with 1968 (Table 17, p. 62) it is clear that the differences are minute and entirely in line with the view that the controls had no independent effect on the inflation rate but might have narrowed the

[a] Figures given are differences between the current month's value of the given interest rate and its value in July 1971. Interest rates: Col (1) 3 month U.S. Treasury Bill rate; Col. (2) Prime Commercial Paper 4–6 months rate; and Col. (3) Moody's Corporate Bond Rate (Aaa). Source of basic data: the Report Appendix C, p. 261, Table C-57.

distribution of wage changes by moving people nearer to the guidepost from both directions.

The effects of the controls on expectations are more striking and clear. Table 2 sets out the cumulative movements of three interest rates from August 1971 to December 1972. It is plausible to attribute the sharp fall in short rates by the end of 1971 to a widely held expectation that the controls would reduce inflation by a substantial amount *in the short run*. However, the behavior of long rates indicates that no such expectation was entertained about the longer run. The long rate was falling steadily month by month throughout the entire period of the Phase I "Freeze" and Phase II with no sharp break in its time path in late 1971. Making firm inferences from data like those set out in Table 2 is not possible since many factors, both domestic and international, are at work and affecting the rates. However, the data do not seem to be inconsistent with the view that the controls moved people's short-term expectations about very sharply but had no perceptible impact on long-term inflationary expectations. Since the actual rate of inflation fell by more than 1 percent point over the period from August 1971 to December 1972 a conventional "error learning" hypothesis would be consistent with a fall in expectations as indicated by the long-term bond rate in the region of 0.56 percent points.

Others than the *CEA* and those cited above have done work on the effects of the 1971–72 wage-price controls.[8] Although there is no general consensus in these papers, the points of substance made in them either agree with the position adopted here, or are challenged by the arguments which I have presented. Also these conclusions are entirely in line with those reached concerning the earlier *U.S.* experiments with guideposts and with the experience of other countries.

The effects of the wage guideposts applied in the early 1960's have been extensively studied. George Perry (1967) found some evidence for a downward pressure on wages during that period. However, criticisms of Perry's work by Paul Anderson, Adrian W. Throop and Michael Wachter, and more recently by Gordon (1972) suggest a consensus view (not shared, perhaps, by Perry) that other labor market variables not related to the guideposts, are capable of explaining Perry's results. Philip Cagan et al. (1972)

[8] See, for example, Gardner Ackley (1972), Barry Bosworth, E. R. Fiedler, M. L. Weidenbaum, and H. S. Houthakker (1972a).

also find it impossible to attribute the behavior of wages in the early 1960's to the guideposts.

Evidence from other countries points in the same direction. In particular, evidence from the *UK*,[9] where experience has been more prolonged and varied, indicates a pattern of response to controls which implies temporary success followed by failure such that, on the average, wage and price inflation rates do not depart from the predictions of econometric models, although the quarter by quarter predictions during controls periods are quite erratic as compared with noncontrolled periods. In fact, price equations display more erratic quarter by quarter behavior than the wage equations during such periods. It could well be the case that Gordon's apparently favorable results on prices are influenced by such erratic behavior, which, for the first three quarters of controls happened to reduce the price change. If so, we can expect to see an over-inflation of prices, relative to wage change in subsequent quarters.

In summary then, it seems that the broad movements in the *U.S.* inflation rate can, with little doubt, be attributed to movements in aggregate demand while the independent effects of the controls suggested by the Report (and others) are hard to find, except as transitory phenomena affecting short-run inflationary expectations.

II. Demand Management

The broad strategy of demand management policy[10] has two features. First, the indicator of appropriate policy is presented as the money value of *GNP*; "... the appropriate policy goal in the ensuing period would seem to be a steady increase of money demand (money *GNP*) at a rate consonant with the potential growth rate of the economy and reasonable price stability" (p. 73). It is suggested that a rate of 9 percent is indicated for 1973. How this should be translated into prices, real output, and employment is only suggested and veiled with qualifications. The best guesses are presented as 6 percent (or more) for real output; 3 percent (or less) for prices and unemployment at around $4\frac{1}{2}$ percent. There is clearly, however, no firm commitment, especially to this last figure.

The second feature of the policy strategy concerns the manner of approach to "maximum employment." "... [T]he behavior of the economy in the near future will be determined not only by whether it is operating below or above some numerical potential output or below or above some target rate of employment, but also by the speed and manner with which it approaches the range of its potential levels" (p. 72).

Three questions seem to be raised by this overall strategy for fiscal and monetary policy and by the detailed judgments which lay behind the projections for 1973. First, is the pursuit of some numerical target for the money *GNP* growth rate, rather than some numerical target for the unemployment rate, appropriate? Second, is a gradual approach to full employment a necessary feature of sound demand management policies at the present time? Third, are the predicted movements in the unemployment rate, the inflation rate and level of money *GNP* compatible with each other, and if not, which of them looks like missing its target?

The broad strategy seems to me to be well conceived. It might be described as a sophisticated monetarist approach to demand management. A simple-minded monetarist approach argues that a target growth rate for the money supply will give the maximum stability since any random or other variation in real aggregate spending

[9] See especially Parkin, Sumner, and Jones.

[10] See the Report, ch. 3, pp. 71–74.

will be damped off by associated changes in interest rates. The best objection to this view points out that there are lags in the operation of monetary policy, which lags are presumably present whether such policy is being used actively to initiate a change or passively to damp out changes being initiated elsewhere. On the other hand, fiscal policy operates more quickly and hence variations in aggregate demand might be smoothed out even more completely than they could by monetary policy alone if a money stock expansion rule is augmented by discretionary fiscal policy. However, if fiscal and monetary policy are to be used together and used successfully to stabilize the level of economic activity at or near its maximum output level then, in effect, aggregate demand becomes perfectly inelastic with respect to the general level of prices and wages. In such a situation, the levels of prices and wages and their inflation rates will be determined purely by self-fulfilling expectations on the supply side. This price level inelasticity of aggregate demand can only be avoided if fiscal and monetary policy makers are willing to see some fluctuation in the level of real economic activity and the overall level of employment.

One possible approach is that suggested by the Report, namely to announce a target rate of expansion for money *GNP* and then to leave the private sector, through competitive price fixing and free collective bargaining, to make decisions about wage and price levels in the light of the authorities' announced money *GNP* expansion rate and the underlying trends in real productivity. A tendency to overinflate wages and prices would, in such a situation, result in a rise in the unemployment rate and a slow down in the real expansion rate. A tendency to underinflate wages and prices would have the reverse effect. There would be a built-in mechanism of the expectations augmented Phillips curve type for adjusting the rate of wage and price inflation, albeit at a price. Also, by announcing well ahead of time the planned underlying growth rate of money *GNP and further sticking to those plans*, the authorities can give maximum help to the expectations mechanism. If a target growth rate for money *GNP* is announced and adhered to, and if people come to believe the authorities intentions with regard to money *GNP* expansion, then the implied underlying inflation rate might become widely and firmly expected and hence the underlying actual rate of wage and price adjustment should be broadly in line with that expectation and give rise to minimal unintended adjustments in the overall level of real activity and employment. Controlling money *GNP* has the further virtue that although macro-economic control is less than perfect, control of this particular magnitude is easier than control of either the real component or the price level component separately.

While approving of the broad strategy of monetary and fiscal policy, I have some doubts about the precise details and numerical magnitudes that have been adopted for 1973. A great deal of emphasis is placed by the Report on avoiding "too fast a dash" for the maximum output target on the grounds that the behavior of the economy depends not only on the level of demand but also on the speed with which that level is approached. It is clearly right that a rapid increase in demand, other things equal, will be more inflationary than a gradual increase. It does seem, however, from simulation studies, that provided the economy does not overshoot its natural unemployment rate, then a rapid approach does not have such serious consequences. Recent simulations of the wage price blocks of three large econometric models of the United States indicate that what is most important is not to overshoot. The speed of approach to the full

employment zone whilst not unimportant, is a secondary matter. This is particularly clear in the simulations reported by Albert Hersch.[11] Hersch shows that in a simulation running forward from 1973 through into the 1980's starting out with an inflation rate of 5 percent and an unemployment rate somewhat below 4 percent that if unemployment is allowed to rise for two and one-half years to the neighborhood of 6 percent and then allowed to fall during the next two and one-half years to the neighborhood of $4\frac{1}{4}$ percent the inflation rate will fall off, slowly at first, and then more quickly to the region of $2\frac{1}{2}$ percent. As the unemployment rate settles down at its $4\frac{1}{4}$ percent rate there will, for two years, be a slight increase in the inflation rate, but only by something of the order of $\frac{1}{2}$ percent. The inflation rate will then settle down to a steady level.

Similar implications seem to follow from the monetarist analysis of Leonall Anderson and Keith Carlson. They present simulations in which a monetarist control rule is operated. They use alternative numerical values for the rule, namely 2, 4, and 6 percent for the growth of the money stock. Although the ultimate inflation rates and the maximum unemployment rates *en route* differ between the three time paths, they nevertheless have a similar broad structure. The unemployment rate rises at first, then comes down fairly sharply eventually overshooting slightly and finally approaching a steady inflation rate from above and unemployment rate from below. What seems to be crucial on the basis of these studies is not that the economy approach its full employment target either asymptotically or particularly gradually. An oscillatory approach of the inflation rate seems to be manageable on the basis of past relations. What is crucial is that the economy does not overshoot *and remain in excess demand for any length of time.*

Is there any danger that the present monetary and fiscal policy stance in the United States may push the economy into such a situation? The answer to this question must depend on the way in which the authorities, in detail, conduct their monetary and fiscal policy during 1973. The broad compatibility of the projected inflation and unemployment rates must at least be queried. Most of the large scale econometric models imply that a long-run unemployment rate of $4\frac{1}{2}$ percent is compatible with an inflation rate of somewhat under 3 percent.[12] However, such models tend to ignore the role of inflationary expectations. These are probably running somewhat ahead of the 3 percent level so that for 1973 a somewhat higher unemployment rate would be indicated as being compatible with an inflation rate of the order of 3 percent. The models which imply no long-run tradeoff would also predict a higher unemployment rate being associated with a 3 percent inflation rate, given the inherited expectations of 1973. If the course of the unemployment rate is given most weight then it is likely that money *GNP* will be allowed to grow more quickly than 9 percent and the inflation rate will pickup. If, on the other hand, the money *GNP* growth target is pursued and adhered to, then it seems likely that the unemployment rate will fall less quickly than projected and fail to achieve the $4\frac{1}{2}$ percent target by the end of 1973 while inflation might well be contained at the $2\frac{1}{2}$ percent to $3\frac{1}{2}$ percent range.[13]

III. International Monetary Reform Proposals

The central features of the *U.S.* pro-

[11] See also G. de Menil and J. J. Enzler.

[12] See, e.g., de Menil and Enzler, Table 6, p. 307.

[13] It is now (May 1973) clear that money *GNP* is growing much faster than 9 percent and inflation has taken off again.

posals for international monetary reform are first, the phasing out of gold and phasing in of *SDR*s to operate alongside national currencies (primarily the *U.S.* dollar) as international reserve assets and second, a symmetrical exchange rate adjustment mechanism based on reserve changes. Certain aspects of these proposed changes seem to have received too little attention from the Report.

It has been repeatedly pointed out for two hundred years and most recently by Robert A. Mundell (1971) and Harry G. Johnson (1971, 1973) that, in a world in which exchange rates are rigid, the explanation for inflation has to be sought at the level of world aggregate monetary expansion and excess demand and not at a national (or regional) level. An increase in total demand in the United States does not necessarily lead to an increase in the rate of inflation in that country. If the rest of the world is underemployed, then an increase in American demand would spill over through the balance of payments into an increase in demand elsewhere and have little or no effect on the general inflation rate. If, alternatively, the rest of the world is at full employment then an increase in demand in the United States will lead to the emergence of universal inflationary pressures.

The experience of the world economy in the latter part of the 1960's and the 1970's is an excellent example of such a process. With the *U.S.* balance-of-payments deficit running at $30 billion in 1971 and $12 billion in 1972, and with the rest of the world operating at or near its full employment potential, it is not surprising that the world as a whole has been sharing in the *U.S.* current inflation. The introduction of *SDR*s, at a time when, because of the *U.S.* balance-of-payments deficit, world liquidity was rising too quickly, has simply exacerbated the situation. The initial *SDR* allocations of $3.5 billion in 1970, and $3 billion in each of 1971 and 1972, when added to the *U.S.* balance-of-payments deficits of $10 billion (1970), $30 billion (1971), and $12 billion (1972), have given rise to an increase in world reserves of 18 percent between 1969 and 1970, 45 percent in 1970–71, and 21 percent in 1971–72. Clearly, such increases have inflationary effects.

This is not to argue that *SDR*s are, in principle, a source of inflation. Rather, if world liquidity is to be added to via *SDR* creation, *and if the international community is to exercise control* over the rate of liquidity creation, then the *U.S.* balance-of-payments deficit must be brought much closer to equilibrium than it has been since 1969. To achieve this, *U.S.* monetary policy would have to be modified substantially with a (gradual) slowdown in the rate of money creation possibly combined with exchange rate adjustments. If the United States does not take these steps then it cannot eliminate its inflation. Unlike smaller countries, the United States cannot ignore the effects of its policies on the rest of the world and the feedbacks which arise from those effects. Given the pursuit of full employment policies in all countries outside the United States, a rapid *U.S.* monetary expansion rate and associated balance of payments deficit leads to a world wide inflation in which the United States inevitably shares.

On the Effects of Fiscal and Monetary Policy: A Taxonomic Discussion

By Bent Hansen*

Current debate on monetary and fiscal policies is much concerned with the effects of such policies, and of changes in the budget and money supply. I propose here to discuss some taxonomic problems related to the concept of policy "effects." Their resolution bears directly upon the controversy between Keynesians and Monetarists. I shall show that it is largely a sham-dispute, and it will appear that the empirical findings of the Monetarists have little relation to the Keynesian creed. Even negative effects of the budget with strong positive effects of money supply are fully consistent with strong positive effects of fiscal action and weak or strong effects of monetary action.

The examination of the concept of effects of economic policy will be undertaken in relation to a model that is specified so as to include both the conventional Keynesian set-up for determining effective demand, and a credit mechanism that links effective demand to the banking system in the spirit of the Monetarists without in any sense being non-Keynesian. To remain manageable the model is kept relatively simple and thus cannot do full justice to either side. But it does contain the major traditional fiscal and monetary policy instruments in a closed economy, it permits a crucial institutional specification, and is, indeed, in line with models suggested by sophisticated Monetarists such as Karl Brunner and Allan Meltzer.

The debate has been much concerned with the proper choice of exogenous and endogenous variables in macro-models; and for good reasons. For in economics (as in the experimental sciences), the notion of effect is usually defined as the difference between two states with and without a specified intervention (disturbance), and to intervene in a system means in the simplest case to change the value of an exogenous variable. The effect per unit of discretionary policy measure (or disturbance) is then determined by the multiplier, static or dynamic as the case may be, of the exogenous variable with respect to a specified endogenous variable.[1] To speak about the effects of an endogenous variable, on the other hand, does not make sense.[2]

In the theory of fiscal policy we talk, however, not only about discretionary policy but also about built-in flexibility and make a well-established distinction between effects of discretionary measures

* Professor of economics, University of California, Berkeley. I acknowledge valuable criticism and advice from George Akerlof, George Borts, and, in particular, Carl Christ. There has also been much feedback from work along the lines of this paper, on Indian and Pakistani fiscal and monetary policies pursued by Nurun Nabi Choudhry and Jayanta Roy at Berkeley and from students' comments in class. Werner Neu made the experiments referred to in fn. 16. The paper was read at a seminar at the International Monetary Fund in November 1972.

[1] Jan Tinbergen, p. 2, calls this type of policy "quantitative." In the case of "qualitative" policies the intervention takes on more complicated forms.

[2] This point was first made by Paul Samuelson, pp. 142–43, in his distinction between multipliers and "pseudo-multipliers." It is the same logical problem that mars the use of endogenous variables as "indicators" of monetary policy measures or effects as lucidly demonstrated by Brunner and Meltzer, pp. 196–203.

and effects of built-in flexibility. This distinction, as we shall see, carries over to monetary policy. Conceptually, however, the latter effects differ from the former, as defined in the last paragraph. When talking about effects of built-in flexibility, we have in mind the difference between the states of two different economic structures (viz., economies with budgets that do or do not respond automatically to changes in the economy) exposed to the same disturbance. Since the problem here is to isolate something which can be called the effects of budget flexibility, the two economic structures should differ only in regard to whether changes that occur be classified as discretionary (i.e., exogenous) or automatic (i.e., endogenous). This requirement is easily satisfied. For if a given set of data can be considered as generated by a particular set of relations with a certain set of variables selected as the endogenous variables, that given set of data could, of course, be generated by the same set of relations with another set of variables selected as the endogenous variables. We move thus from one economic structure to the other simply by changing variables. What is automatic response in one interpretation is discretionary action in the other one, and vice versa. Clearly, multipliers defined with respect to the same two variables will differ—maybe even with respect to *sign*, as we shall see—as between two such models, although both models describe the same economy. The "automatic effects" of built-in flexibility per unit of disturbance may then be defined as the difference between two such multipliers defined on the disturbance and the endogenous variable in question.[3]

[3] Richard Musgrave's (1959, pp. 508–10) well-known measure of built-in flexibility is based on the *ratio* between two such multipliers. To make the various effects additive it is preferable to work with the difference rather than the ratio. But that is only a matter of convenience.

This point is crucial for what follows in this paper, and it may be useful to illustrate it by an example related to fiscal policy.[4] Consider the differential form of a simple Keynesian system where Y denotes income, I investment, C consumption, G government expenditure, T tax revenue, and t the tax rate:

$$dY = dI + dC + dG$$

$$dC = c_1(dY - dT) + dc_2$$

$$dT = tdY + Ydt$$

The endogenous variables are assumed to be dY, dC, and dT, while the discretionary policy measures are dG and dt (or, Ydt); as exogenous, noncontrolled disturbances we have dI and dc_2. The solution in dY is

$$dY = \frac{dI + dc_2 + dG - c_1 Ydt}{1 - c_1(1 - t)}$$

and the effects, E_{discr}, of discretionary policy actions are

$$E_{discr} = \frac{dG - c_1 Ydt}{1 - c_1(1 - t)}$$

All sets of empirical observations of dY, dI, dC, dG, dT, dc_2, and Ydt that satisfy the above system will also satisfy the same three relations with dY, dC, and Ydt as endogenous variables, and dG and dT as policy parameters. With the system thus interpreted we have the solution

$$dY = \frac{dI + dc_2 + dG - c_1 dT}{1 - c_1}$$

and the effects, E_{total}, of the total changes in government expenditure and revenue will be

[4] See Hansen (1969, ch. 1, II, A).

$$E_{total} = \frac{dG - c_1 dT}{1 - c_1}$$

With the first interpretation the system has built-in flexibility in tax revenues; but not with the second interpretation. The multipliers and, hence, the effects of both exogenous disturbances, such as dI and dc_2, and of discretionary policy measures, such as dG, differ clearly with the two interpretations. And whereas with the first interpretation it does not make sense to ask for the effects of a change in total tax revenues, dT, this question does make sense with the second interpretation. If we now define the automatic effects, E_{autom}, of built-in flexibility in tax revenues as the difference between the effects of the exogenous, noncontrolled disturbances in the system with and without built-in flexibility in tax revenues, we have

$$\begin{aligned} E_{autom} &= \frac{[dI + dc_2]}{1 - c_1(1 - t)} - \frac{[dI + dc_2]}{1 - c_1} \\ &= \frac{[dG - c_1 dT]}{1 - c_1} - \frac{[dG - c_1 Y dt]}{1 - c_1(1 - t)} \end{aligned}$$

It follows that

$$E_{discr} + E_{autom} = E_{total}$$

a relation that applies to any macrotheoretical set-up and will turn out to be crucial for understanding some of the differences between Keynesians and the Monetarists.

The notion of effects of built-in flexibility calls attention to the fact that the classification of variables as endogenous and exogenous depends entirely upon our "point of view,"[5] that is, upon the questions we seek to answer. We may ask for the effects of disturbances or discretionary measures; we may also ask for the automatic effects of built-in flexibility at disturbances in the economy; and we may ask for the total of discretionary and automatic effects in a given situation. All questions are legitimate in the sense that they can be answered, but they do lead to different classifications of variables. And since they lead to different variable classifications, they imply different multipliers and, hence, effects, too. This simple point seems to have been overlooked by Keynesians as well as Monetarists in the debate of monetary policy.

Another circumstance of some consequence for the choice of variables and of crucial importance for our problem is the so-called budget constraint of the public sector. It was recently brought into the debate by Carl Christ in two important contributions (1967, 1968), but has in fact a long history in the theory of economic policy;[6] in practical monetary analysis it is old hat,[7] and, as we shall see, it has indeed been observed in more careful theoretical contributions (for instance, Brunner and Meltzer). To omit the public sector's budget constraint is a fallacy. Crude Keynesian and quantity theory generally ignores it, however; a typical example is

[5] See Karl Popper, p. 106.

[6] The constraint and its importance was probably first discovered by Knut Wicksell (1898, pp. 6f.) in his macroeconomic analysis of the incidence of taxation and it is generally recognized by modern incidence theory. In monetary theory it has been used by Bertil Ohlin (1934, in particular ch. 5; and 1941, two never translated monetary classics). I myself borrowed the notion from Wicksell and Ohlin to discuss the relation between fiscal policy and money supply (1955), (1958), (1967, chs. 3 and 15). In the early Keynesian literature, Abba Lerner's discussion of "functional finance" (1943), (1946, ch. 24, in particular pp. 314–15) and Lloyd Metzler's wealth study (1951) are the outstanding examples—and exceptions. Some examples from balance of payments theory could also be given. In growth theory Alain Enthoven (1960, p. 315) should be mentioned.

[7] The "bank reserve equation" of the Federal Reserve System is perhaps the best known example; see *The Federal Reserve System, Purposes and Functions*, chs. 12 and 13. A variation on the same theme is the traditional IMF analysis of the "counterpart of money supply changes" that appears in any IMF mission report; see, for instance, *International Financial Statistics*, "Monetary Survey," any country table, any year.

Milton Friedman's recent disclosure (1970) of his monetary system.

I. The Public Sector Budget Constraint

This constraint expresses the fact that net flow of central bank money from the public sector equals net increase of the stock of central bank money held by the private sector and is, indeed, nothing but the change in the central bank's balance sheet between specified points of time. Including creation of central bank money, the public sector is no less constrained in its planning of expenditure and revenue than the household is by *its* budget constraint. Exactly how the constraint should be written depends, however, upon the institutional setting. It would seem that two *Idealtypen* appear in the literature, each one idealizing actually existing arrangements. One of them could be called the European type of constraint, the other one, the United States type of constraint; but with the United States in mind, they could perhaps also be called the pre-Accord and the post-Accord constraints, respectively.

Disregarding foreign transactions (which are easily included), the balance sheet of a central bank that issues currency, keeps deposits (reserves) for and gives loans to commercial banks, and serves as the bank of the government (the Treasury) is

$$L^b + L^g = M^n + M^b$$

where M^n is currency in circulation, M^b commercial banks' deposits at the central bank, L^b rediscounts and advances to commercial banks, and L^g net claims on the government held by the central bank. The change in the balance sheet between two points of time can be written as

$$\begin{aligned}\Delta M^n + \Delta M^b &= \Delta L^b + \Delta L^g \\ &= \Delta L^b + \Delta G - \Delta T + \Delta B \\ &\quad - \Delta B/r_g + D_0\end{aligned}$$

where G is government purchases of goods and services, T tax revenues, B number of government bonds held by the private sector (perpetuaries with \$1 interest payment per period, the only type of claims on the government considered here), r_g bond market rate of interest, and D_0 the budget deficit (government net borrowing) at the beginning of the period. Defining as usual the supply of central bank money, the monetary base, as $M_0 = M^n + M^b - L^b$, we have

$$\Delta M_0 = \Delta G - \Delta T + \Delta B + D_0 - \Delta B/r_g$$

The sum of the first four terms on the right side is the total deficit of the budget (government net borrowing); the last term, $\Delta B/r_g$, is the dollar amount of debt management and open market operations in government bonds.

This form of the constraint could be called the European type of public sector budget constraint; it is the form considered by Christ (1967, p. 436), (1968, p. 56). In a closed economy of this type the supply of central bank money can only change through a deficit (surplus) of the cash budget and through debt management and open market operations; we do not need to distinguish between these two kinds of bond operations provided that all central bank profits are paid to the budget and central bank open market operations are limited to government securities. On the other hand, net cash payments cannot be made to or from the budget or through debt management and open market operations without affecting the supply of central bank money. The budget constraint thus rules out the possibility of studying "isolated" changes in the supply of money or (other) isolated policy measures, and it compels us to specify exactly how money supply changes, through the budget, through operations in the market, or exchange operations (if included), to

mention the three major inroads of money in a modern institutional setting.

We may, however, imagine another ideal type of arrangement in which the government does not at all use the central bank as its banker and thus does not draw upon or keep deposits with the central bank, but to the last nickel finances cash deficits and surpluses through financial transactions with the private sector, in our simplified case through debt management market operations in government bonds. The central bank may, nonetheless, buy and sell government bonds at its own discretion in the open market. We would then have two public sector constraints, one for the central bank which we shall write so that the left side is equal to the change in net central bank money supply, ΔM_0,

$$\Delta M_0 = \Delta M^n + \Delta M^b - \Delta L^b = - \Delta B_{CB}/r_g$$

where $-\Delta B_{CB}$ is the number of government bonds bought by the central bank in the open market, and another constraint for the government (Treasury)

$$\Delta B_{Tr}/r_g = \Delta G - \Delta T + \Delta B + D_0$$

where ΔB_{Tr} is the number of bonds sold by the Treasury to the private sector, and $\Delta B = \Delta B_{Tr} + \Delta B_{CB}$. With these constraints the supply of central bank money can only change through a central bank open market operation; and any budgetary transaction is matched by a corresponding debt management operation in the open market. These two budget constraints represent together what we could call the *U.S.* type; it is the form used by Brunner and Meltzer[8] (1967, p. 208, equation (A 5)). The Accord between the U.S. Treasury and the Federal Reserve System in 1951 could perhaps be described "as if" a shift from the European to the *U.S.* type of constraint took place.[9]

It is immediately clear that what can be done under one of these budget constraints can also be done under the other one. Budget deficit financing through the central bank, which on the European constraint simply means that the treasury draws upon the central bank, must on the *U.S.* model take place through Treasury sales of bonds in the open market to cover the deficit, accompanied by simultaneous central bank purchases in the market to the same amount. The outcome of such concerted discretionary actions will be the same under the two systems. In this sense we might just as well consolidate the two constraints in the *U.S.* type system to the single European type constraint. This, however, would hide the fact that *automatic* responses are different with the two systems. An automatic increase of tax revenue (during an upswing, say) implies with the European constraint an increase of government deposits at the central bank and a corresponding decline of the net supply of central bank money. With the *U.S.* constraint it would leave central bank money supply unchanged but diminish the supply (stock) of government bonds held by the private sector. On the European model the events would imply a "tightening" of the credit market with an upwards pressure on interest rates and a fall in total private wealth; on the *U.S.* model the bond interest rate would fall, while private sector net wealth might fall or increase, and it is more difficult to say what would be the net result. Thus it matters whether a country applies the European and the *U.S.* type of constraint; the effects of built-in flexibility will differ.

[8] In an unpublished paper Brunner and Meltzer (1971) have presented a hybrid form of constraint. See also Brunner (1961).

[9] Strictly speaking the Accord meant, of course, that the Fed stopped automatically supporting the government bond rate at a low level.

In neither Europe nor the United States do we find these *Idealtypen* in pure breed. Some European countries (Germany and Belgium, for instance) are really on the *U.S.* model. And governments always have some working balances with the central bank through which deficits or surpluses may temporarily be financed. In the United States, the Treasury can borrow from the Federal Reserve System to a limit of $5 billion; the Treasury does, on the other hand, keep deposits with the Federal Reserve Banks, although its debt management operations (from the more infrequent bond issues to the weekly Treasury bills auctions) nowadays aim at preventing substantial balances with the Federal Reserve Banks from being built up; in addition, the Treasury simply moves deposits from the Reserve Banks to commercial banks, and vice versa. "By carrying the bulk of its deposits in tax and loan accounts [with commercial banks] the Treasury moderates the effect on bank reserves of fluctuations in its receipts and payments" (*The Federal Reserve System*, p. 194). The intentions are undoubtedly, since the time of the Accord, that it should be up to the discretion of the Federal Reserve Board to decide whether or not it will change its net claims on the government and, hence, the supply of central bank money. These being the intentions it seems justified to approximate the *U.S.* system by assuming the existence of two independent public budget constraints.

In the very short term and for small changes the European and the *U.S.* set-up may not be different; the immediate adjustments may take place on Treasury accounts with the central bank or the commercial banks in either system. But the short term for which this is true may be so short (a few days, a week at most) that it is of little interest in a macroanalysis that centers upon the interaction of real and financial sectors and markets. In the following we shall consider both types of constraints not only because countries are different in this regard, but also, and in particular, because Keynesians generally have tended to think with the European type of constraint in the back of their minds, while American Monetarists naturally have the *U.S.* type of constraint in front of their minds.

II. Model with Fiscal and Monetary Systems

Consider now the following economic relations for an economy with a budgetary and monetary system. The precise specification is not too important for the purpose of taxonomy. We have

$$(1)\qquad Y = I + C + G$$

$$(2)\qquad C = c_1(Y - T + B) + c_2(M^n + \alpha M^b + B/r_g) + c_3$$

$$(3)\qquad I = i_1 r_b + i_2 Y + i_3$$

$$(4)\qquad T = t_1 Y + t_2$$

$$(5)\qquad M^n = nY$$

$$(6)\qquad \alpha M^b = m_1(r_g - \mu r_b) + m_2 Y + m_3 B/r_g$$

$$(7)\qquad \overline{K} + I = (\alpha - 1)M^b + L^b$$

$$(8)\qquad L^b = \beta_1(r_b - \bar{r}) + \beta_2$$

New variables are: $\overline{K}$ is initial private stock of real capital, r_b commercial banks' loan rate, μ is ratio between commercial banks' deposit and loan rates, $\bar{r}$ is central bank's discount rate, α is inverse of required reserve ratio.

We shall assume the signs of constants and parameters to be: $c_1>0$, $c_2>0$, $i_1<0$, $i_2>0$, $t_1>0$, $n>0$, $m_1<0$, $\mu>0$, $m_2>0$, $m_3>0$, $\beta_1>0$ and $B>0$. The choice of signs is in all cases obvious except perhaps $B>0$, there might exist countries with net government claims on the private sector.

Our relations assume that households receive all income and that all private saving is made by households. They own notes, government bonds, and bank deposits but have no bank loans. Enterprises in return finance exclusively through bank loans; this assumption obviously helps to give the banks a crucial role. Total financial wealth of households is thus equal to central bank notes plus bank deposits plus value of government bonds; wealth appears in the consumption function, equation (2), and the demand function for deposits, equation (6), and in the omitted demand function for bonds.[10] We ignore value of ownership, capitalized value of future tax payments, direct benefits of government services, and the like. Enterprises and commercial banks have zero net worth. The investment function, equation (3), contains the commercial banks' loan rate and national income as arguments. Both consumption and investment function are thus highly conventional and acceptable to Keynesians.

The treatment of the banking system suffices to make it an important part of the economy and introduces two important monetary policy instruments, the central bank discount rate and the reserve ratio. Central bank money is divided between currency held by the households and the commercial banks' claims on the central bank, the reserves. The reserves may be counted gross or net because the commercial banks may borrow from the central bank. Demand from households for currency is proportional to national income, equation (5). Equation (6) has on its left side total supply of bank deposits and on its right side total demand for deposits from households. Demand for deposits depends upon the difference between bond rate and deposit rate (the latter assumed to be kept by the banks in fixed proportion, μ, to the loan rate), national income, and households' government bond holdings. We do not distinguish between demand and time deposits and this may be a dangerous simplification (Lyle Gramley and Samuel Chase; Karl Brunner, 1969). The left side of equation (6) may also be read as the inverse of the required reserve ratio times the required, legal reserve, M^b; on this reading the equation determines the legal reserves. The supply of bank loans to enterprises is $(\alpha-1)M^b+L^b$, the right side of equation (7). The term L^b is commercial bank loans (advances or rediscounts) from the central bank or, if negative, the excess reserves of the commercial banks. On the left side of (7) we have the demand for loans from enterprises; it is equal to the (predetermined) total stock of real capital at the beginning of the period plus the investments of the period. We disregard commercial bank investments in government securities (bonds or Treasury bills), another important omission because it prevents us from studying debt management policy in detail. The last equation,

[10] By virtue of Walras' Law we have left out the households' demand function for bonds and the equilibrium condition for the bond market. If we let B^d/r_g denote demand for bonds (in value terms) the equilibrium condition is $B^d/r_g=B/r_g$ and the demand function for bonds is $B^d/r_g=Y[1-(1-t_1)c_1-t_1-n-m_2]-m_1(r_g-ur_b)-t_2(1-c_1)+(1-c_2)(M^n+\alpha M^b+B/r_g)+(1-c_1)B+m_3B/r_g$, which makes sense, given the signs of the constants. In the derivation of this (short-term) demand function for bonds we do not assume that total net worth is given and constant. The instantaneous rate of change of net worth is equal to savings which in our setting may be positive or negative.

The bond market demand equation implied by our model does not suffer from a basic flaw in standard Keynesian models. It is easy to show that, for instance, the standard *IS-ML* model, or Klein's Keynes model assume a kind of Say's Law for bonds so that an increase in the supply of bonds automatically (that is at given income, prices and interest) creates a corresponding increase in the demand for bonds (Hansen (1970, pp. 134–37), Akerlof). Our model thus allows for the "crowding-out" from the financial markets of private borrowers when the government finances a deficit by sales of securities (see Spencer and Yohe where the main references are given).

finally, specifies the commercial banks' demand for central bank loans, or excess reserves as a function of the difference between their own loan rate and the discount rate of the central bank. The higher their own loan rate is, the stronger is the incentive to borrow from the central bank or the weaker is the incentive to keep excess reserves; the higher the discount rate is, the more expensive are central bank loans and the stronger is the incentive to keep excess reserves rather than running the risk of having to borrow from the central bank. These assumptions are in line with current theory.

We have already discussed possible public sector budget constraints and definitions of money supply. All ingredients of both central bank money supply, $M_0=M^n+M^b-L^b$, and money supply in the wider sense, $M_2=M^n+\alpha M^b$, are included in the model and we could add these two equations to the system.

Systems like (1) to (8), completed with a public sector budget constraint, can be used for studying long-term equilibria where the system has come to rest with a balanced budget and a constant amount of money (Christ (1968), also Lerner). It would be entirely unrealistic, however, to assume that the authorities should remain passive during a process toward a long-term stationary state (that may not exist). It is more likely that they would continuously work on rectifying the short-term position. Assuming that the period coincides with the budget year, we shall therefore concentrate on the development from one short-term position to the next and study the effects of economic policy with this short-term perspective, taking for granted that during each period new policy measures will be taken (Christ (1967)). The specification of the available policy instruments may thus conveniently be made in relation to a corresponding differential model (Christ (1967), Hansen (1969, ch. 1, II, A)), determining a change in the short-term equilibrium position. We have

$$(1') \qquad dY = dI + dC + dG$$

$$(2') \qquad dC = c_1dY - c_1dT + c_1dB + c_2dM^n + c_2\alpha dM^b + c_2M^bd\alpha + c_2dB/r_g - c_2\frac{B}{r_g^2}dr_g + dc_3$$

$$(3') \qquad dI = i_1dr_b + i_2dY + di_3$$

$$(4') \qquad dT = t_1dY + Ydt_1$$

$$(5') \qquad dM^n = ndY$$

$$(6') \qquad \alpha dM^b + M^bd\alpha = m_1dr_g - m_1\mu dr_b + m_2dY + m_3\frac{dB}{r_g} - m_3\frac{B}{r_g^2}dr_g$$

$$(7') \qquad dI = (\alpha - 1)dM^b + M^bd\alpha + dL^b$$

$$(8') \qquad dL^b = \beta_1dr_b - \beta_1d\bar{r}$$

We have then to add a public sector budget constraint and, as already pointed out, we have a choice between (at least) two types, describing different behavioral patterns of budgetary and monetary authorities. With the European type of constraint we have

$$(9') \qquad dM^n + dM^b = dG - dT + dB + D_0 - dB/r_g + dL^b$$

whereas the $U.S.$ type of constraint would require the following specification:

$$(9'a) \qquad dM^n + dM^b = dL^b - dB_{CB}/r_g$$

$$(9'b) \qquad dB_{Tr}/r_g = dG - dT + dB + D_0$$

$$(9'c) \qquad dB = dB_{CB} + dB_{Tr}$$

III. Policy Instruments and Endogenous Variables

Thus including a public sector budget constraint of the European type, our system consists of nine equations and we have to select the same number of endogenous variables. Assuming from the outset that in a capitalist economy without direct controls dY, dC, and dI are endogenous variables to be explained by the model, we are left with eleven "policy variables"—dG, dT, dt_1, dB, dr_g, dr_b, $d\bar{r}$, $d\alpha$, dL^b, dM^n, and dM^b—as possible candidates for the other six endogenous variables. The remaining five policy variables are the policy parameters to which effects could be ascribed. From our relations we could thus derive no less than $11!/6!(11-6)!=462$ different models. Even assuming that effects of discretionary measures should only be evaluated in terms of income, dY, there would still be $462\text{x}5=2310$ different effects (multipliers) to calculate; there would, for instance, be 210 different expressions for $dY/d\bar{r}$ (assuming, of course, that all models have sensible solutions). And yet, we have not included the two definitions of money supply which would give us thirteen policy variables from which to choose five.

With a *U.S.* type of constraint we would have eleven equations, and, granted again that dY, dC, and dI be endogenous, we would have thirteen policy variables, the above mentioned plus dB_{CB} and dB_{Tr}, among which to choose eight other endogenous variables. Including the two definitions of money supply we should have fifteen variables to choose among. Our choice is even wider than with the European specification.

If we had no principles for selecting endogenous and exogenous variables, we would have to leave everything like that and be satisfied by presenting all these alternative interpretations and effects. This seems in fact to be what Christ (1967, 1968) recommends. With respect to appraisal of past and present policies, we would thus end up in pure agnosticism; for if we cannot specify what were the policy measures taken, we cannot tell what were the effects of the policies pursued. And with respect to future policy we may give advice that nobody knows how to follow (such as recommending 5 percent increase per year of money supply in the wide sense without specifying the instruments to be used for this purpose).

It should first be noticed, now, that the

Table 1—Summary of Models Investigated

introduction of public budget constraints itself limits our choice of exogenous variables somewhat. At least one variable in a constraint must be endogenous, and when only one of the variables in a constraint is endogenous, unacceptable implications may follow. The public budget constraint(s) limit our choice of exogenous variables, but they do not really serve as positive guides for this choice. To this end some "point of view" has to be specified, i.e., some question has to be asked, and some sort of a priori information has to be brought into the picture.

We may, on the one hand, be interested in appraising actual policy actions of the past and present and/or predicting future effects of policy actions to be taken. If so, we have to direct our attention to institutional matters and ask how economic policy actually was, is, or is to be conducted. We have to study past and present procedures and actions of authorities to find out "which variables are under the command of the government" to use Tinbergen's expression (p. 7). With the notable exception of Milton Friedman and David Meiselman (see later) this seems also to be the way most of the participants in the debate look at matters (see, for instance, James Tobin, p. 165).[11]

If, on the other hand, we were interested in problems of budget flexibility and monetary flexibility rather than appraising discretionary policy actions, we would have to consider not only the actual systems with their response patterns but, in addition, an alternative hypothetical system of comparison with different response patterns. Studies of actual administrative systems may help us to choose the hypothetical, comparative system in which somehow budget and monetary flexibility has been removed; but ultimately this choice is a matter of taste.

In this paper we study the effects of discretionary measures in two different models, with European and *U.S.* budget constraints, respectively, and effects of total changes in budget and money supply in three different models, with European budget constraint and money supply defined as central bank money and money supply in the wide sense, respectively, and with the *U.S.* constraint and money supply in the wide sense. Finally we shall show how the automatic effects of built-in flexibility in budgetary and monetary systems can be separated and related to effects of discretionary measures, fiscal and monetary. Table 1 summarizes the characteristics of the models. The discussion is concentrated on the model with European budget constraint in Sections IV.A and V.A. with and without built-in flexibility in budget and money supply.

IV. The Effects of Discretionary Fiscal and Monetary Measures

A. *Model with European Type of Constraint*

We shall now assume that for the particular country and period whose policy actions we want to appraise, the European type of constraint is relevant and that the controlled policy instruments actually were (are) G, t_1, B, $\bar{r}$, and α so that the discretionary measures taken are dG, Ydt_1 (in \$ value), dB, $d\bar{r}$, and $d\alpha$. The endogenous variables are the differentials of Y, C, I, T, r_g, r_b, M^n, M^b, and L^b; see Table 1.

Solving the system for dY, we obtain

$$(10') \quad dY = \frac{1}{\Delta} \text{ [a multiplicand]}$$

[11] Michael J. Hamburger has suggested purely statistical (econometric) criteria for the classification of variables. It is clear, however, that we are confronted here with an analytical problem that cannot be solved by inductive methods; see, for instance, Peter Frost.

The individual terms of the multiplicand are identified in the following tabulation:

I: impact of autonomous change in demand

$dc_3 + di_3 \cdot (\delta_1)$

II: impact of discretionary changes in expenditure and revenue

$+ dG - c_1 Y dt_1 + c_1 dB$

III: impact of discretionary changes in expenditure and revenue via central bank money supply

$+ (dG - Ydt_1 + dB) \cdot (\delta_3)$

IV: impact of initially existing deficit via money supply

$+ D_0 \cdot (\delta_3)$

V: total impact of debt management operations

(i) impact via stock of bonds

$$+ c_2 \frac{dB}{r_g}$$

(ii) impact via bond rate of interest

$$+ \frac{dB}{r_g} \cdot (\delta_2)$$

(iii) impact via central bank money supply

$$- \frac{dB}{r_g} \cdot (\delta_3)$$

VI: impact of change in reserve requirement

$+ M^b d\alpha \cdot (\delta_4)$

VII: impact of change in discount rate

$+ \alpha d\bar{r} \cdot (\delta_5)$

Equation 10′ is a usual multiplier expression; $1/\Delta$ is the multiplier. Our assumptions about the signs of constants and parameters do not suffice for determining the sign of Δ. We assume that it is positive. Apart from autonomous consumption, dc_3, all the exogenous variables appearing in the multiplicand are weighted in various ways. Like Δ, the weights δ_1 to δ_5 are complicated, tedious combinations of the constants and parameters of the model. For our purpose we do not need to write them explicitly. With our assumptions the sign of δ_1 is indeterminate, δ_2 and δ_5 are negative, δ_3 and δ_4 are positive.

We shall comment upon the individual terms of the multiplicand. The expressions inside the multiplicand we call the "impacts"; when multiplying impacts by multiplier we obtain the "effects."

Term I is the impact of autonomous changes of demand. These are the exogenous, nonpolicy disturbances. The impacts of autonomous consumption and investment differ in size, the reason being that in our model investment implies a demand for bank loans, savings a demand for government bonds; investment and savings work thus in different ways on the credit markets. Note that we cannot be sure that the impact of autonomous investment is positive.

Term II is the direct impact on demand of discretionary fiscal measures dG, Ydt, and dB. The term dB is the increase of government interest payments related to the period's bond sales. It seems natural to include changes in interest payments with other fiscal measures, although, strictly speaking, they are the outcome of debt management and open market operation decisions. Terms I and II will be recognized as good "Keynesian" terms (with a small reservation for autonomous investments)[12] working directly on effective demand.

[12] The weight, δ_1, of autonomous investment has the form $1+\epsilon_1$ where ϵ_1 (negative) is a combination of the constants α, β_1, i_1, m_1, m_3, n, c_2, and B/r_g^2, all of them re-

Term III is particularly interesting from our point of view. It shows the impact of all discretionary fiscal policy measures via the change in supply of central bank money which they directly imply. Since this impact works through changes in money supply it might seem reasonable to call Term III the monetary impact of discretionary fiscal measures and to count it as part of monetary policy. Keynesians might, nevertheless, want this impact to be credited to fiscal policy; it arises after all only because fiscal measures are taken and is, indeed, a kind of mirror image of these measures. The sign of this term is positive; thus, its inclusion among the effects of fiscal policy would certainly strengthen the Keynesian position.

Term IV is, of course, the Lerner-effect of "functional finance." If there is a cash deficit in the initial position, central bank money supply will increase automatically with this amount. This is a predetermined effect from the budget that will exist as long as the budget is not balanced. We are up against the same classification problem as with Term III. The sign is positive and the term may be important, particularly if the deficit is large. Terms III and IV could be consolidated into $(dG-Ydt_1+dB+D_0)\delta_3$; this term would be the impact from the change in central bank money supply implied by initial deficit and discretionary fiscal measures together. Note, however, that this consolidated term does not include automatic changes in tax revenues and thus cannot be described as the impact of the total deficit. Nor is it equal to the total change in central bank money supply; even if we included $-dB/r_0$ (from term V, iii (see below)), it would still not include those changes in central bank money supply that are induced by automatic tax revenue changes.

Term V collects the impact of debt management and open market operations; analytically there is no difference between these two kinds of operations. The term is split up into three subterms according to the way through which the impact is exerted. There are impacts via the change in the stock of bonds (i), via the accompanying change in households' cash balances (iii),[13] and via the capital gains or losses associated with changes in the bond rate (ii). While the sign of Term V as a whole is indeterminate, the sign of the subterm (i) is positive, and those of subterms (ii) and (iii) are negative. Thus we cannot say a priori whether open market operations are expansive or contractive. How should this term be allocated in relation to fiscal and monetary policy? To exclude the open market operations of the central bank from monetary policy would seem odd; to split the term in two parts according to whether the operations are carried out by central bank or Treasury does not make much sense, either, because the effects are identically the same.

Terms VI and VII are certainly the outcome of monetary policy. They are the impact of reserve requirement and discount rate changes. The signs of the weights of these monetary measures are positive and negative, respectively, as should be expected.

Any attempt to classify the effects of policy measures thus runs into ambiguities. At one extreme we have a classification which counts only Term II as fiscal policy

lated to the monetary system. The impact of autonomous investment could, thus, be broken down in $di_3+di_3\epsilon_1$ of which the first term is the direct "Keynesian" impact on effective demand, and the second one is the impact through monetary repercussions and might be counted as part of the monetary effects.

[13] Lerner, p. 311, pointed out that the effects of taxes and borrowing cannot be clearly separated because, in addition to taking income and adding to people's assets, respectively, both imply a drain on money supply and thus overlap to some extent. This is precisely the reason why we find Ydt_1 in both Terms II and III, and dB/r in both Terms V (i) and V (iii); Ydt_1 in Term III and $-dB/r_0$ in V (iii) have the same weight, δ_3.

impact, and considers all the other terms from III to VII as impacts of monetary policy;[14] and at the other extreme, one that classifies Terms II, III, IV, and V as fiscal (or, at least, budgetary) policy impacts, and only leaves Terms VI and VII as monetary policy impacts. And in between we have several alternatives to choose amongst. Even if we single out Term V and call it the impact of debt management and open market operations, and include the latter in monetary policy, we are still left with the problem of classifying Terms III and IV. The most natural reaction to these ambiguities might be simply to give up the idea of classifying everything into fiscal and monetary policy, and work with all the individual terms of the multiplicand that model and selection of policy instruments give rise to.

Does money matter in this model? This question may be interpreted in two different ways. Does it matter whether there exists a monetary system, and how it is organized and how it functions? Does it matter, given the monetary system, whether the quantity of money is larger or smaller, or changes? On both interpretations money certainly matters in this model, although we cannot ascribe definite, well-defined effects to the total changes in money supply; but we have well-defined "liquidity effects."

B. *Model with U.S. Type of Constraint*

We use here equations (1′) to (8′) and (9′a), (9′b), and (9′c). We shall assume that the discretionary measures are dG, dt_1, $d\alpha$, $d\bar{r}$, and $dB_{CB}/r_g(=-dM_0)$. For the endogenous variables, see Table 1. In terms of policy measures the difference between the two types of models is that in the European type model all transactions in government bonds, dB/r_g, were considered a discretionary measure; in the present model only the central bank open market operations in bonds have this position. Treasury operations, dB_{Tr}/r_g, are endogenous and do not have well-defined effects. The implication is that changes in the supply of central bank money can be considered a discretionary policy measure with well-defined effects equal to, and indistinguishable from, the effects of open market operations (with opposite sign).

Solving for dY we now get

$$(10'\text{a}) \quad dY = \frac{1}{\Delta'}\,[\text{a multiplicand}]$$

the terms of the multiplicand being:

I: direct impact of autonomous changes in demand

$$dc_3 + di_3(\delta_1')$$

II: direct impact of discretionary budgetary measures

$$+\,dG - c_1 Y dt_1 + c_1 dB_{CB}$$

III: impact of discretionary budget changes and initial budget deficit via implied increase of stock of bonds

$$+\,(dG - Ydt_1 + dB_{CB} + D_0)(\delta_3')$$

IV: impact of change in reserve requirements

$$+\,M^b d\alpha(\delta_4')$$

V: impact of change in discount rate

$$+\,\beta_1 d\bar{r}(-\alpha\delta_4')$$

VI: impact of open market operations

$$+\,dB_{CB}/r_g(\delta_6')$$

The multiplier is $1/\Delta'$, assumed to be

[14] Even part of the impact of autonomous investment could be included here; see fn. 12.

positive. The terms δ' are weights (different from the δ in (10′)); with our assumptions δ'_3 and δ'_4 are positive and δ'_5 is negative, while the sign of δ'_1 is indeterminate.

We note first that the impacts of both government spending (dG) and increased central bank money supply ($-dB_{CB}/r_0$) are positive: a priori we cannot say which impact is the largest one.

The division between effects of fiscal and monetary policies is simpler in this case than with the European type constraint. Not even Term III really gives rise to ambiguity. This (positive) term shows the impact of the increase of private sector bond holdings, accompanying an increase of expenditure or a fall in revenue. Note that this term cannot be considered the impact of debt management operations because it does not show the impact of *sales* of bonds against money (Term VI shows the impact of such sales), and Keynesians might rightly claim credit to fiscal policy for this term; without a budget deficit or surplus this change in government bonds with the private sector would not take place. Since Term III is definitely positive its inclusion in fiscal policy will again strengthen the Keynesian position.

V. The Total Effects of Fiscal and Monetary Policy

We turn now to the other point of view—the problem of built-in flexibility and its consequences. For that purpose we have first to set up a system which is equivalent to the system consisting of equations (1′) to (8′) (with the relevant budget constraint(s)) in the sense that a given set of data which could have been generated by the first system could just as well have been generated by the new system, but differs from the first system in having no built-in flexibility, either in the budget items or in money supply. On the basis of such a system we can consider the *total* changes in government expenditure and revenue, and in the supply of money as government policy measures and study their effects (briefly, the total effects); and we shall use it in Section VI for defining the automatic effects of built-in flexibility in budgetary and monetary system in line with the introductory remarks.

We have clearly to consider T as an instrument and dT as a policy measure. Consequently, we have either to discard equation (4′) or consider dt_1 as an endogenous variable. These two methods of procedure are equivalent. With respect to debt management and monetary policy we shall distinguish between the European and the *U.S.* type of constraints.

A. *Model with European Type of Constraint and M_2 as Policy Variable*

We continue to interpret dB and dB/r_0 as exogenously determined; otherwise, there would be some built-in flexibility even in the current budget via interest payments. A moment's reflection makes it clear that it is not possible to remove all built-in flexibility with respect to the monetary system. For if no automatic changes were to take place in the balance sheet of the central bank, and the reserve requirements as well as the discount rate were still to be considered as controlled by the central bank, we would have no less than eight exogenous variables, namely—in addition to dG, dT and $dB-dL^p$, dM^n, dM^b, $d\bar{r}$, and $d\alpha$. The model would in return contain only six endogenous variables and would be overdetermined. With respect to the remaining three endogenous variables the choice is rather arbitrary, but in line with current debate it would be natural to let either central bank money

or money supply in the wider sense appear as policy parameters. Since Monetarists are vacillating between these definitions of money supply (and others) it may be appropriate to study the implications of shifting from one money supply to the other as exogenous policy variable.

Choosing first money supply in the wider sense as the exogenous variable, we add to our equation system a new equation:

$$(11') \quad dM_2 = dM^n + \alpha dM^b + M^b d\alpha,$$

which we obtain from $M_2=M^n+M^b\alpha$. We consider dM_2 as an exogenous policy measure and dM^n and dM^b as endogenous variables, so that the composition of the change of money supply is endogenously determined. In addition, we shall choose to let commercial banks' borrowing, dL^b, and the discount rate, $d\bar{r}$, appear as endogenous. To let the central bank's discount rate appear as endogenous is, of course, unusual in the sense that the discount rate now appears as a kind of "market" rate; it just means, however, that the central bank "follows" the market. In any case, this one is an "as if" model, where we are only interested in getting built-in flexibility removed from budget and supply of money, and we remove it at the cost of assuming built-in flexibility in marginal tax rate, i_1, and discount rate, $\bar{r}$.

We thus work with the system consisting of equations (1′) to (8′), (9′) and (11′). The policy measures are dG, dT, dB, $d\alpha$, and dM_2. Endogenous variables are shown in Table 1. It is clear that a set of data generated by the present model could also have been generated by model (1′) to (8′) and (9′). This is so because we could always add equation (11′) to that model and interpret dM_2 as an endogenous variable.

Solving for dY we now obtain

$$(10^*) \quad dY = \frac{1}{\Delta^*}\,[\text{a multiplicand}]$$

the terms of the multiplicand being:

I: impact of autonomous changes in demand

$$dc_3 + di_3(\delta^*\mu m_1)$$

II: impact of total changes in expenditure and revenue

$$+\, dG - c_1 dT + c_1 dB$$

III: impact of total cash deficit via change in central bank money supply

$$+\,(dG - dT + dB + D_0)(\delta^*\mu m_1 - 1)$$

IV: impact of debt management and open market operations

$$+\,\frac{dB}{r_g}\,(1 + c_2 - \delta^*(\mu m_1 - m_3 i_1))$$

V: impact of change in money supply in wide sense

$$+\, dM_2(1 + c_2 - \delta^*(\mu m_1 + i_1))$$

where $\Delta^* = 1 - c_1 - \delta^*(i_2\mu m_1 + i_1(n + m_1))$; we assume Δ^* to be positive. In the weights of the multiplicand we have the common factor

$$\delta^* = \frac{c_2}{m_4 i_1}\,\frac{B}{r_g^2}, \text{ sign positive}$$

and

$$m_4 = m_1 - m_3\,\frac{B}{r_g^2}, \text{ sign negative}$$

We first note a peculiarity: changes in reserve requirements, $d\alpha$, do not appear in the multiplicand, although $d\alpha$ belongs to our policy measures, the reason being that it has zero effects. Its effects are, as it were, absorbed in the (endogenous) changes of

the discount rate; and changes in the discount rate have no effects because it is endogenous. Thus the Monetarist would be justified in concentrating on the effects of changes in money supply in the wider sense.

A second striking feature is that autonomous investments, di_3, enter with a *negative* weight (m_1 being negative). This remarkable result is related to the position of the banking system with the assumption of money supply, dM_2, being exogenous. An increase in investments requires an increase in bank loans. Given the reserve ratio, bank loans can increase if M^b increases which at given dM_2 and α can only happen if currency circulation falls, which in turn requires that income fall. Bank loans can also increase at given M_2 if bank borrowing from the central bank, L^b, increases, but this requires an increase in interest rates, which will again help to keep back investments and via wealth accomplish a fall in consumption. This fall in consumption must be so strong that we get a fall in income despite some expansion of investments. It should be emphasized that this result does not hinge upon the magnitude of responses to interest rate changes, but only upon their signs.

Looking at Terms II and V we see that both government spending and money supply have positive weights, but while that of spending, dG, is equal to one, that of money supply>1. Transfers (dT and dB) have the weight $c_1<1$. A priori, we can thus state that the effects of money supply exceed those of changes in budget expenditure and revenue. And things get even worse for the Keynesians when we note that in Term III we have the monetary impact of the budget deficit through changes in central bank money supply implied by the deficit, and the weight of this term is negative and <-1. If we consolidate Terms II and III we get

$$dG(\delta^*\mu m_1) - (dT - dB)(c_1 + \delta^*\mu m_1 - 1) + D_0(\delta^*\mu m_1 - 1)$$

where both dG, $-(dT-dB)$, and D_0 appear with negative weights. What is usually considered expansive fiscal policy thus implies a fall in income. With the monetary effects of budgetary changes and the deficit included in the effects from the budget, we thus end up with negative effects of fiscal policy and positive effects of changes in money supply in the wide sense. Which settles matters definitely in favor of the Monetarists.

Again it may be asked why we obtain the remarkable result that Keynesian "expansive" policies, a budget deficit, increased spending and a fall in taxes all have negative effects on income. And again the key to the answer is in the assumption that money supply in the wide sense is kept constant despite the increase of central bank money supply. A glance at equation (9′) shows immediately that if for instance dG is positive ($dT=dB=D_0=0$) so that central bank money increases via the budget, then at given note circulation, M^n, and bank borrowing, L^b, bank reserves, M^b, must increase by an amount equal to dG through an increase of deposits. The value of M_2 has thus increased by dG and to prevent a further increase through the bank's expanding their loans on the basis of the reserve increase, the central bank rate has to increase so much that commercial bank loans from the central bank fall, and/or excess reserves are built up by the amount dG. But this still leaves the nonbank sector with the initial increase in deposits equal to dG and at given required reserves bank loans to investments (see equation (7′))have to be cut down by this amount. Thus investments will fall by dG and the expansionary effects of the increase in government ex-

penditure through the Keynesian part of the system will be completely offset: there is no increase in income. This is the "crowding out" mechanism that the St. Louis school emphasizes (Spencer and Yohe). However, the only way (in our model) for the banks to adjust loans downwards is through an increase in the bank loan rate which through substitution between deposits (including time deposits) and bonds will pull up the bond rate. There is thus a fall in private wealth: consumption and, hence, income will now fall. "Crowding" in the credit market with wealth effects on consumption are thus ultimately responsible for the negative effect on income of an increase in government expenditure. There is nothing mysterious in this result.

Finally we have in Term IV the impact of debt management and open market operations. It can be broken down in subterms as we did in (10′). The weight has an indeterminate sign. We are left with the problem of whether this term should be counted as monetary or budgetary policy, be kept separate as debt management policy, or be divided according to who makes the operations.

To make the best possible of the situation for the Keynesians we should consider Term III as monetary policy impact which, if needed, could be neutralized by appropriate debt management or open market operations. The impact of changes in expenditure and revenue is then of the order of magnitude usually claimed by Keynesians (albeit definitely smaller than the impact of a change in money supply). But it should then be noted that irrespective of whether fiscal policy is expansive or contractive we have simultaneous monetary effects (partly predetermined) working through the budget, and these effects are "perverse," that is, contractive or expansive depending upon whether there is a total deficit or surplus.

B. *European Constraint and M_0 as Policy Variable*

If instead of M_2 we had chosen net central bank money supply,

$$(11'a) \qquad M_0 = M^n + M^b - L^b$$

as the exogenous policy variable, we would be forced to let dB/r_g appear as endogenous because the public sector budget constraint would be $dM_0 = dG - dT + dB - dB/r_g + D_0$. At least one of the variables in the constraint must be endogenous, and with D_0 and r_g predetermined and dM_0, dG, and dT exogenous, we have no other choice than to let dB be endogenous. This means that we have some flexibility in the budget, viz. *via* the interest payments; and we cannot speak about effects of debt management and open market operations. Since interest payments and their flexibility may be considered a secondary problem, we might be willing to accept working with dB as endogenous. Policy variables and endogenous variables are shown in Table 1. The solution for dY is then

$$(10^{**}) \quad dY = \frac{1}{\Delta^{**}}\,[\text{a multiplicand}]$$

the terms of the multiplicand being:

I: impact of autonomous changes in demand

$$dc_3\delta_1^{**} + di_3(1 - \delta_2^{**})$$

II: impact of total changes in expenditure and tax revenue

$$+\, dG - c_1 dT$$

III: impact of total deficit (disregarding interest payments) via stock of bonds

$$+\, (dG - dT + D_0)\delta_3^{**}$$

IV: impact of reserve requirement and discount rate changes

$$+ (M^b d\alpha - \alpha\beta d\bar{r})\overset{**}{\delta_4}$$

V: impact of changes in central bank money supply

$$+ dM_0(\alpha\overset{*}{\delta_4} - \overset{*}{\delta_2} - \overset{*}{\delta_3})$$

where it can be shown that all δ are positive assuming $-m_1 < \alpha\beta/\mu$. The weight of dM_0 is positive and so is the weight of dG. A priori we cannot say which one is largest. Interest payments do not appear in Terms II and III and there is no term, of course, for impact from bond transactions. Once more, we have the problem of how to classify Term III. And we note that now both reserve requirement and discount rate changes appear with monetary policy impacts besides money supply. At comparison between (10*) and (10**) we find that while the effects of money supply in the wide sense definitely exceed those of fiscal policy (which even become negative when monetary effects are included), it is not possible a priori to say whether the effects of central bank money supply exceed or fall short of those of fiscal policy. Monetarists will be strikingly right if we concentrate on money supply in the wide sense; Keynesians may be right if we concentrate on central bank money supply.

C. *Model with U.S. Type of Constraint*

Things work out somewhat differently with the *U.S.* type of budget constraint, as could be expected. Since the institutional setting here is arranged in advance so as to prevent flexibility in central bank money supply, we do not need to ask how to remove this kind of flexibility. The Accord took care of that (by and large). On the other hand, if we insist on keeping the characteristic feature of the budget constraint unchanged, viz. that cash deficits or surpluses always be financed through debt management operations with the private sector, we have to continue to let debt management operations, dB_{Tr}/r_g, be endogenous; thus we cannot remove budget flexibility with respect to interest payments. Quantitatively this may perhaps be considered a secondary matter. We have, then, three possibilities with regard to the set-up of exogenous variables:

(a) We can select dG, dT, $d\alpha$, $d\bar{r}$, and $dB_{CB}/r_g(=-dM_0)$ as exogenously determined policy variables. The only difference to the previous solution (10′a) of the *U.S.* type of model is that flexibility in tax revenue is now removed.

(b) We can select dG, dT, $d\alpha$, dB_{CB}/r_g $(=-dM_0)$, *and* dM_2. In this case both central bank money supply and money supply in the wide sense are exogenously determined policy variables; no Monetarist has, however, had such a possibility in mind (for instance, discussing the effect of an increase in the monetary base at unchanged money supply in the wide sense). We shall leave this possibility aside.

(c) We could, finally, select dG, dT, $d\alpha$, $d\bar{r}$, and dM_2, implying that we remove flexibility in money supply in the wide sense, but permit flexibility in central bank money supply. To reintroduce flexibility in M_0 means, however, switching to the European type of constraint, we have already studied this case (equation (10*)).

We have thus in effect only one case, (a), to consider with the *U.S.* type of constraint. We work accordingly with a model consisting of equations (1′) to (8′), and (9′a), (9′b), and (9′c), and assume that the exogenous policy variables are dG, dT, $d\alpha$, $d\bar{r}$, $dB_{CB}/r_g(=-dM_0)$. The endogenous variables are shown in Table 1. The solution for dY is

$$(10^{*a})\quad dY = \frac{1}{\Delta^{*a}}\,[\text{a multiplicand}]$$

the terms of the multiplicand being:

I: impact of autonomous changes in demand

$$dc_3 + di_3(\delta_1^{*a})$$

II: impact of total changes in budget expenditure and revenue

$$+ dG - c_1 dT + c_1 dB_{CB}$$

III: impact of total cash deficit via implied increase of private sector bond holdings

$$+ (dG - dT + dB_{CB} + D_0)(\delta_3^{*a})$$

IV: impact of changes in reserve requirements

$$+ M^b d\alpha(\delta_4^{*a})$$

V: impact of changes in discount rate

$$+ \beta_1 d\bar{r}(-\alpha\delta_4^{*a})$$

VI: impact of open market operations (change in central bank money supply with opposite sign)

$$+ \frac{dB_{CB}}{r_g}(\delta_5^{*a})$$

with $1/\Delta^{*a}$ being the multiplier (again, too tedious to write down) assumed to be positive. The coefficients δ_3^{*a} and δ_4^{*a} are positive, δ_5^{*a} is negative, while the sign of δ_1^{*a} is indeterminate.

Note that Terms II and III do not include change in interest payments arising from Treasury transactions in bonds, and strictly speaking these terms do not comprise the *total* changes in expenditure and revenue and the deficit. The interpretation of Term III is the same as that of Term III in (10′a). Both Term II and VI are positive, and we cannot say a priori whether a change in budget expenditures and revenue or central bank money supply has the strongest effect, even if we include Term III in fiscal policy.

Note also that our results in this section and the previous ones are at variance with those of William Silber.

VI. The Effects of Built-In Flexibility in Budgetary and Monetary System

By the automatic effects of built-in flexibility of budget and monetary system together we shall, in line with the remarks in the introductory paragraphs, understand the difference between the effects of noncontrolled disturbances on national income at the actual budgetary and monetary systems, and at a hypothetical system with no built-in flexibility.

To fix ideas, we shall assume that system (1′) to (8′) with the European constraint (9′) and dG, dt_1, dB, $d\alpha$, and $d\bar{r}$ as policy parameters accurately describes the actually existing system and its administrative *modus operandi*. System (1′) to (8′) with (9′) and (11′) and dG, dT, dB, $d\alpha$, and dM_2 as exogenous policy variables is then a hypothetical system without built-in flexibility in budget and money supply in the wide sense. (See Table 1.) Instead of tax rate and discount rate we let tax revenue and money supply play the roles as policy parameters.

If we let E_{autom} denote the automatic effects of all built-in flexibility thus specified, we have from solutions (10′) and (10*), dc_3 and di_3 being the nonpolicy disturbances,

$$(12)\quad E_{autom} = \frac{1}{\Delta}\,[dc_3 + di_3\delta_1] - \frac{1}{\Delta^*}\,[dc_3 + di_3\delta^*\mu m_1]$$

From (10′) and (10*) it follows that we could also write

$$(12') \quad E_{autom} = \frac{1}{\Delta^*}\Big[dG - c_1 dT + c_1 dB + \frac{dB}{r_g}(1 + c_2 - \delta^*(\mu m_1 - m_3 i_1)) + (dG - dT + dB + D_0) \cdot (\delta^* \mu m_1 - 1) + dM_2(1 + c_2 - \delta^*(\mu m_1 + i_1))\Big] - \frac{1}{\Delta}\Big[dG - c_1 Y dt_1 + c_1 dB + \frac{dB}{r_g}(c_2 + \delta_2 - \delta_3) + (dG - Y dt_1 + dB + D_0)\delta_3 + M^b d\alpha(\delta_4) + \alpha\beta_1 d\bar{r}(\delta_5)\Big]$$

We want to split E_{autom} into automatic effects of the budget and the monetary system, respectively. Two problems arise. How shall we deal with debt management operations? And once again we are confronted with the question of whom to credit for the monetary implications of fiscal action. To exemplify, we shall here show the definitions that follow from including monetary implications of fiscal actions and budget changes in fiscal policy, but leave debt management and the monetary implications of the initial deficit in monetary policy.

We then naturally define the automatic effects of the budgetary system, $E_{aut.budg.}$, as

$$(13) \quad E_{aut.budg.} = \frac{1}{\Delta^*}[dG\delta^*\mu m_1 - (dT - dB) \cdot (c_1 + \delta^*\mu m_1 - 1)] - \frac{1}{\Delta}[dG(1 + \delta_3) - (Y dt_1 - dB)(c_1 + \delta_3)]$$

If, moreover, we agree that the automatic effects of the monetary system, $E_{aut.mon.}$, should be defined so that $E_{aut.mon.} + E_{aut.budg.} = E_{autom}$, we have from (12′) and (13)

$$(14) \quad E_{aut.mon.} = \frac{1}{\Delta^*}\Big[\frac{dB}{r_g}(1 + c_2 - \delta^*(\mu m_1 - m_3 i_1)) + D_0\delta^*\mu(m_1 - 1) + dM_2(1 + c_2 - \delta^*(\mu m_1 + i_1))\Big] - \frac{1}{\Delta}\Big[\frac{dB}{r_g}(c_2 + \delta_2 - \delta_3) + D_0\delta_3 + M^b d\alpha(\delta_4) + \alpha\beta_1 d\bar{r}(\delta_5)\Big]$$

Defining, furthermore, the effects of discretionary budgetary measures, $E_{discr.budg.}$, and monetary measures, $E_{discr.mon.}$, as (see 10′)

$$(15) \quad E_{discr.budg.} = \frac{1}{\Delta}[dG(1 + \delta_3) - (Y dt_1 - dB)(c_1 + \delta_3)]$$

and

$$(16) \quad E_{discr.mon.} = \frac{1}{\Delta}\Big[\frac{dB}{r_g}(c_2 + \delta_2 - \delta_3) + D_0\delta_3 + M^b d\alpha(\delta_4) + \alpha\beta_1 d\bar{r}(\delta_5)\Big]$$

and recalling that the effects of nonpolicy disturbances when there is no built-in flexibility in budget or money supply in the wide sense, $E_{non-policy}$, is

$$(17) \quad E_{non-policy} = \frac{1}{\Delta^*}[dc_3 + di_3\delta^*\mu m_1]$$

we have the total change in national in-

come broken down upon the (total) effects of nonpolicy disturbances, discretionary fiscal and monetary policy measures, and automatic effects from built-in flexibility in budgetary and monetary systems, thus

$$(18)\quad dY = E_{non-policy} + E_{discr.budg.} + E_{discr.mon.} + E_{aut.budg.} + E_{aut.mon.}$$

Finally, we remind the reader about the two basic ambiguities in this definitional system: the removal of flexibility in budget and monetary system can be made in several ways, and the individual impacts can be distributed as fiscal and monetary policy differently from what we have done here. An obvious possibility is to single out bond sales as a separate policy (which will then have both discretionary and automatic effects) or, perhaps, distribute them on budgetary and monetary authorities. Similar expressions could be worked out for the model with the United States type of constraint. Since our main concern is concepts and definitions, we shall not enter upon the problem of the size of automatic effects in different systems although this must be an important consideration in the choice of institutional system.

VII. Some Implications for the Friedman-Meiselman Controversy

In their attack on Keynesian theory, Friedman and Meiselman (1963), (later referred to as F-M), tested the following hypotheses (we leave out the price variable which is of no relevance for what follows):

$$(19a)\quad C = a + VM$$

or

$$(19a')\quad dC = da + VdM$$

$$(19b)\quad C = a + KA$$

or

$$(19b')\quad dC = da + KdA$$

$$(19c)\quad C = a + VM + KA$$

or

$$(19c')\quad dC = da + VdM + KdA$$

thus explaining consumption by "money only" ((19a) in which V is velocity), by "autonomous expenditure only" ((19b) in which A is autonomous expenditure and K the multiplier), and finally by "both money and expenditure" (19c). F-M chose to use C as a dependent variable for purely statistical reasons. A number of definitions of M were tried out; they ended up with a definition corresponding to our M_2 (currency in public circulation plus adjusted demand deposits plus time deposits in commercial banks; see F-M, (1963) p. 184). A was defined as private domestic investment *plus* the government deficit on income and product account, *plus* the net foreign balance.

F-M's methods were criticized partly for misspecification, partly for statistical reasons. Here we shall comment mainly on the first problem.

F-M (1963, p. 174) were, of course, fully aware that the hypotheses to be tested depend upon the specifications of the basic structural models of which the second and third equations are reduced forms. There is little point in demonstrating this acknowledged fact. In deriving the reduced forms, however, nobody tried to derive the combined form from a basic structural model, and it must, of course, be the combined form upon which interest should center. Albert Ando and Franco Modigliani did set up a model containing both budget variables and money supply, but the model was mainly used for discussing the conditions for the extreme first and second hypotheses (19a) and (19b) to follow from the model as reduced forms. Thus, it may perhaps be of some interest

to compare F-M's third reduced form with the form we would obtain from equation (10^*) or (10^{*a}) if we were to remove all autonomous elements from the left side of the equation.

We single out equations (10^*) and (10^{*a}) rather than ($10'$) and ($10'a$) because F-M explicitly wanted to work with money as one of the explanatory variables, and with the total (change of the) deficit included in the so-called autonomous expenditure, the other explanatory variable. This means that their equations (19a), (19b), and (19c) must be interpreted as reduced forms of models without any kind of built-in flexibility in budget and money supply in the wide sense. There is nothing wrong in that, as we have seen. The criticism raised against F-M by all participants of the discussion[15]—that they confuse autonomous and induced variables, particularly with respect to budget revenue and money—was thus misdirected. F-M were to that extent entirely justified in ridiculing this objection. Granted that, it should not be overlooked, however, that the effects that F-M tried to measure were the effects of total budget and money supply changes which lump together effects of discretionary measures and automatic effects of built-in flexibility and thus are of no relevance for appraising actual discretionary policy measures taken in the past and present, and (probably) in the future. F-M's findings are relevant for appraising policy actions only in the country of Erehwon; they would, however, become of great interest for evaluating past and present developments were they confronted with corresponding estimates of the effects of discretionary measures because they would then allow us to draw conclusions about the stabilizing or destabilizing properties of budget and monetary systems.

[15] Ando and Modigliani; Michael DePrano and Thomas Mayer (1965); Donald Hester.

Starting out, then, from equation (10^*) we obtain after deducting the autonomous part of dY,

$$(10^{*\prime})\quad dY-dc_3-di_3-dG = \frac{1}{\Delta^*}\Big[dc_3(1-\Delta^*)+di_3(\delta^*\mu m_1-\Delta^*) + dG(\delta^*\mu m_1-\Delta^*) - (dT-dB)(c_1+\delta^*\mu m_1-1) + \frac{dB}{r_g}(1+c_2-\delta^*(\mu m_1-m_3 i_1)) + D_0(\delta^*\mu m_1-1) + dM_2(1+c_2-\delta^*(\mu m_1+i_1))\Big]$$

This expression, compared with F-M's third reduced form (19c′), on differential form, gives rise to the following observations:

(i) Equation (10^*) is based on a model with the European type of budget constraint. It may be questioned to what extent this model is adequate for the *U.S.* economy after the Accord of 1951, and before the Great Depression. When dM_2 is exogenous, however, we had no other choice than to switch back to the European type of constraint. In a different model this might perhaps not be so. If the comparison had been between the effects of central bank money and budget changes on the basis of equation (10^{*a}), we could, and probably should, work with different models (different budget constraints) before and after 1951. This would lead to different specifications of the regression equations for different periods. F-M use the same specification for all periods.

(ii) Equation ($10^{*\prime}$) implies that autonomous expenditure, dA, should be defined as

$$dA = dc_3(1-\Delta^*) + (di_3 + dG)(\delta^*\mu m_1 - \Delta^*) - (dT - dB)(c_1 + \delta^*\mu m_1 - 1)$$

instead of

$$dA = d(I + G - T + B)$$

which corresponds to F-M's definition (disregarding the foreign deficit). The term A should thus be the weighted sum of the individual items. Only in the simplest Keynesian models where $\Delta^* = 1 - c_1$ can weighting be escaped (DePrano and Mayer). Since the weights of the individual items are composed of coefficients in the basic model and are unknown, we would have to use dc_3, $di_3 + dG$, and $dT - dB$, with D_0, dM_2, and dB/r_g as separate explanatory variables in a regression analysis. Similar points were made by Ando and Modigliani.

(iii) The exclusion of the autonomous parts of dY from the left-hand side of ($10^{*\prime}$) implies that the multiplier effects dc_3, di_3, and dG are reduced by one, whereas those of $dT - dB$, dB/r_g, D_0, and dM_2 remain unchanged. This was, of course, pointed out by F-M (1963, pp. 176 and 205); but both they and other participants in the discussion seem to have overlooked that whereas $1/\Delta^*$, the general multiplier, has to be positive for the system to be stable (if this is thought necessary), there is nothing to prevent $1/\Delta^* - 1$, the consumption multiplier (of dc_3 in our model) from being negative. F-M found negative consumption multipliers and correlation coefficients between autonomous expenditure and consumption for a number of periods and declared this to be "the most puzzling result we have found" (1963, pp. 203 and 212). Nothing could be less puzzling; it only requires that $1/\Delta^* < 1$, that is $\Delta^* > 1$. This suffices to make the effects of autonomous consumption, dc_3, negative. And the effects of $(di_3 + dG)$ and $-(dT - dB)$ are in any case negative with our model. With the specifications of our model, F-M should indeed expect to find negative multipliers for what they call autonomous expenditure.[16] And apart from the simplest Keynesian models, the consumption multiplier may always be negative.

On the other hand, it cannot be sufficiently emphasized that for the very same economy which gave us negative effects of total budgetary changes, we should find positive effects of discretionary fiscal measures, equation (10′) and they might even be larger, dollar by dollar, than the effects of discretionary monetary measures. If this were what the Keynesians have in mind, both parties could be perfectly right, asking different questions to the same set of economic relations.

(iv) We are led to consider the numerical size of Δ^*. Our assumptions about

[16] Also the St. Louis econometricians, Leonall Anderson and Jerry Jordan (1968) (1969) find systematically small positive or negative effects (usually insignificant) effects on *GNP* of their fiscal indicators with strong and significant positive effects of money supply in the wide sense. Their fiscal indicators are, however, open to criticism. It is also interesting to note that when corresponding regressions are made with the rate of interest as the monetary policy variable, the crowding effects of government spending seem to disappear; fiscal policy then appears with strong effects (Spencer and Yohe, p. 23; M. Keran (1970)). This is precisely what we should expect with our model when we give up M_2 as exogenous variable and uses $\bar{r}$ instead.

Anderson and Jordan work with distributed lags in their reduced forms and their statistical estimates show invariably that fiscal policy has positive effects on Y in the first period(s) but that effects thereafter become strongly negative. By lagging all monetary variables in the behaviorial equations of our model, experiments show that our model on an appropriate choice of coefficient values can reproduce exactly the same time pattern of the response of income to fiscal policy changes: positive effects in the first period(s), followed by stronger negative effects. From our discussion of the individual terms in equation (10*) it is easy to understand why this is so. It is the repercussions through the financial part of the system that makes the ultimate results differ from standard Keynesian thinking, and if these repercussions are lagged the Keynesian relations will dominate in the beginning but sooner or later be wiped out by the financial reactions.

the signs of the constants and parameters do not guarantee $\Delta^*>0$, but do not prevent $\Delta^*>1$, either. If m_1 is numerically small, this condition may be fulfilled; if, further, c_2, B, i_1, i_2, or μ are sufficiently large (numerically) we will indeed have $\Delta^*>1$.

(v) Note also that in regression analysis of the reduced forms we would probably have to use the solution on the form of (10*′), where Terms II and III of (10*) are consolidated. Otherwise, we might run the risk of a high degree of collinearity between the explanatory variables. For empirical analysis we might thus not even have the option of excluding the so-called monetary effects of budgetary changes from the effects of total fiscal changes to escape the negative effects of the latter.

(vi) Given the general multiplier, $1/\Delta^*$, we know that (with Terms II and III of (10*) consolidated) the effects of budget changes are negative and those of changes in money supply positive. Inspection of the weights in (10*′) shows, moreover, that both are numerically larger, the larger are c_2, i_1, and m_1 (numerically). In other words, large wealth and interest responses increase the effects of money supply as compared with the (negative) budgetary effects. By insisting on large wealth and interest responses, Keynesians may thus be doing harm to their own case, provided that the issue is the total effects. With respect to the effects of discretionary measures, however, this does not hold true.

(vii) Finally, the specification of F-M's third hypothesis is open to objections, quite apart from the definition of dA. First, debt management and open market operations implying changes in the privately owned stock of government bonds are not included in their regressions. This is a misspecification; only if they had chosen to let all bond transactions appear as endogenously determined would it have been correct to leave out government bonds in the regression equation; but in that case we would have had to let the discount rate appear as an exogenous variable and a determinant in the regressions.

(viii) Second, our model leads to the inclusion of the initial budget deficit as an explanatory variable in the differential model, in addition to the (weighted) changes in the budget. F-M included the budget deficit in their original equations and on differentiation only the change in the deficit should appear as an explanatory variable. There is no doubt that F-M at this point have been perfectly faithful to conventional Keynesian theory; the appearance of the deficit itself is at variance with basic Keynesian thinking, excepting Lerner; and is closely related to the recognition of the public sector budget constraint. Models that respect that constraint on public sector behavior will always come out with the budget deficit itself as an explanatory variable when working on first differences.
